INTRODUCTION

Molybdenum does not commonly occur in mine-mill effluents. It is also an element of little or no environmental concern. Despite years of investigation AMAX, INC., the largest producer of molybdenum in the world, and the U.S. EPA as well as the state of Colorado, have yet to find a case where molybdenum has been responsible for environmental damage. Excessive molybdenum in livestock water supplies can, however, give the trots to cattle. Why then should molybdenum be removed from water?

First, if there is enough of it, molybdenum removed from effluents may one day represent a profitable resource although that is not the case at current prices. Second, regulatory limits have been promulgated in some states, apparently motivated by the attitude of some regulators that everything should be regulated on principle, and molybdenum should have to be removed to meet some arbitrary standard "In case there are environmental effects

that are not yet known." One can always hope that a new trend toward more pragmatic regulatory attitudes may one day dawn.

OCCURRENCE OF MOLYBDENUM IN THE MINE-MILL ENVIRONMENT

Molybdenum is mined as a primary product as molybdenite MoS_2 in several porphyry deposits in the western U.S.A. and Canada. It also occurs as a by-product of copper mines in the U.S.A., Canada, and several South American countries, notably Chile and Peru.

Molybdenum also occurs in volcanic formations associated with and/or overlying primary uranium deposits in the southwestern U.S.A. and is sometimes associated with other minerals (e.g., uranium, tungsten and gold) in breccia pipe deposits scattered throughout the western U.S.A.

In the mining and milling of primary molybdenum deposits, e.g., at Climax, Henderson, Colorado, etc., residual particles of MoS_2 in the tailings may oxidize with time to release small concentrations of molybdenum to the seepage water and tailings decant solutions. Drainage from wasterock dumps may also contain some molybdenum. Molybdenum in minewater and tailings seepage and decant water from the Climax Mine was described by GOTT and LAFFERTY (1978) and by RAMADORAI (1978).

In uranium ore milling, molybdenum can build up in process solutions or occur in mine drainage.

At in situ leach test projects for uranium recovery from deep deposits in New Mexico, molybdenum was identified in the leach liquor that was pumped from the wellfield and represented a potential metallurgical interference in the ion exchange uranium recovery process.

Molybdenum also occurs associated with the gold ores recently discovered in the major Hemlo gold district and is expected to range between 0.5-3.0 mg/l in wastewater from this operation before being treated and below 1.0 mg/l in the discharged effluent.

The PEDCO (1983) report provides an interesting insight into approximate ranges of molybdenum levels in mine-mill effluents. In the case of some mine categories, e.g., taconite, phosphate, etc., molybdenum was not considered important enough to be included in the investigation. On the other hand, elevated molybdenum levels in effluents, process water, and leachates were observed for molybdenum, copper, and gold-silver recovery operations. A question arises as to whether molybdenum may possibly be a pathfinder element for gold mineralization in volcanic environments.

Molybdenum was generally found in the PEDCO (1983) investigation to occur in mill tailings decant solutions, minewater, and leachates of tailings solids, wasterock, and ore in a range of 0.002-2 ppm but averaging less than 0.5 ppm. Examples of industry classes where molybdenum exceeded 1 ppm are considered unusual except in some uranium, molybdenum, copper, and gold districts:

SUMMARY OF PEDCO (1983) DATA

	Average (ppm)	Number of Samples	Maximum (ppm)
NEW MEXICO URANIUM DISTRICT			
Surface Mine Waste and Leachate	LT 0.01	4	LT 0.01

	Average (ppm)	Number of Samples	Maximum (ppm)
OTHER GOLD-SILVER DISTRICT			
Tailings Pond Liquid	0.827	4	1.80

The fact that molybdenum occurs in minewater and/or tailings pond decant solution and tailings leachate by no means implies that it presents an environmental or groundwater contamination problem. Most of the operations where molybdenum occurs in this way are in the western U.S.A. where there is net evaporation and can be operated for zero discharge. Due to heavy winter snowfall, this may not always be possible as, for example, at the Climax Mine. The Henderson Mine and Mill is, however, a zero discharge operaton as are most Nevada gold-silver operations.

Elsewhere in the west as, for example, at NORANDA's Brenda Mine and other molybdenum/copper operations located in areas with net precipitation, zero discharge is not possible, and water must be discharged eventually. In one copper-molybdenum operation in British Columbia, 1,500 acre feet per year of water are added to the tailings impoundment. Thus far, the tailings pond has been expanded to contain the excess water, but this will not be possible indefinitely. It is believed that during the last few years, a significant amount of water was discharged from the impoundment and that this met with regulatory disapproval to the extent that an alternative long-term solution is required. It is not exactly clear why excess solutions cannot be discharged after a straight forward lime addition and settling (or HDS) to remove other heavy metals if molybdenum is not environmentally damaging. In British Columbia, most drainage eventually leads to salmon rivers, and possibly regulators are not prepared to risk any possibility of damage to fisheries.

ENVIRONMENTAL SENSITIVITY - MOLYBDENUM

Molybdenum up to several ppm in water has not been identified as the cause of any environmental damage so far.

HELLUMS and BAILEY (1979) referred to studies on molybdenosis in 1965 and 1972 in which it was found that areas that had been used for stockpiling uranium ores "during the old AEC days" showed a high rate of molybdenosis in cattle. This condition was caused by the effect of windblown ore dusts and surface water transport of copper and molybdenum to the dietary intake of cattle locally. This study reinforced the state of Texas' determination to isolate tailings permanently. Information on the molybdenosis studies could be requested from:

WILLIAM E. HELLUMS
Supervisor of Industrial Licensing
Radiation Control Branch
Division of Occupational Health
and Radiation Control
Texas Dept. of Health
Austin, TX

EDGAR D. BAILEY
Administrator
Radiation Control Branch
Division of Occupational Health
and Radiation Control
Texas Dept. of Health
Austin, TX

High levels of molybdenum can upset ruminants such as cattle and impart to them the trots. Apparently, grazing irrigated by water containing high concentrations of molybdenum may affect cattle in this way. Information on evaluation of environmental sensitivity to molybdenum might be available from:

AMAX, INC.
1707 Cole Blvd.
Golden, CO 80401
(303) 234-9020
James Gilliland

AMAX would, of course, be interested in knowing about any reputed effects of molybdenum on the environment anywhere in the world.

REGULATORY LIMITS FOR MOLYBDENUM

Molybdenum is of such little environmental concern that it is not included in state and federal reviews of their water quality objectives. However, some mine-mill operating and NPDES permits do include a regulatory limit for molybdenum in their effluents.

Limits for molybdenum in effluents were identified in the following small number of operating permits:

Operation	Limit (ppm)	Permit Type
AMAX, Mount Emmons	2.0	Daily Limit NPDES
Climax Molybdenum Mine	2.0	24 Hour Maximum NPDES
New Mexico Water Quality Control Commission 8/27/1971	0.01	General Discharge Limit

TREATMENT FOR MOLYBDENUM REMOVAL

Straightforward lime precipitation and settling does not effectively remove molybdenum from acid solutions, especially in very cold climates or else AMAX would have employed it.

Discussion of molybdenum removal from effluents in operating plants is very limited, and two papers on the development and evaluation of processes for molybdenum removal along with other metals by GOTT and LAFERTY (1978) and by RAMADORAI (1978) are inserted below. These papers were written by employees of AMAX, INC.

Also included below is a copy of U.S. Patent 4,219,416 issued to RAMIREZ and RAMADORAI (1980) describing a process for recovering molybdenum from effluents employing co-precipitation with iron and dissolved air flotation (using electrolytically generated gas bubbles).

Subsequently it is believed that dissolved air flotation using mechanically generated bubbles was tested with encouraging results. Suppliers of reputedly suitable DAF units are:

POLLUTION CONTROL ENGINEERING, INC.
10751 South Lakewood Blvd.
Downey, CA 90241
(213) 861-1297

ENVIREX-WATER QUALITY CO.
Division of Rexnord
1901 South Prairie Avenue
Waukesha, WI 53186

To date, no commercial-scale examples of DAF for metals precipitate removal from effluents have been identified.

BIOLOGICAL REMOVAL OF MOLYBDENUM

As far as frontier technologies are concerned, an interesting example of biological metals removal is described by BRIERLEY, et al. (1980) for which the abstract is inserted below.

ACTIVATED CHARCOAL ADSORPTION OF MOLYBDENUM

FAULKNER (Undated) refers to the use of activated carbon in the mid-'50's to remove molybdenum from acid uranium circuits which became an established practice although at this time few if any uranium operations are believed to use activated carbon for this purpose.

Development of Waste Water Treatment at the Climax Mine

by Richard D. Gott and John M. Laferty, Jr.

Prepared for the
1977 American Mining Congress
San Francisco, California

Introduction

Since the 1930's Climax Molybdenum Company has operated a water recycle system utilizing active tailing dams and water storage facilities to collect mill water and return that water for reuse in the plant. This system allowed total containment of waste water, except during the annual spring snow melt period. The rapidly increasing runoff into the tailing system made it necessary to discharge some industrial water to keep the total system in balance. Annual discharge, occuring historically between April and June, averaged 2,400 acre feet per year and was bled into Ten Mile Stream at a controlled and monitored rate to maintain stream quality.

In addition to the recycle system, seep water pump facilities have long term been incorporated below each tailing dam at individual drainage areas to pick up all seep water for return into the tailing system.

Climax, desiring to go to a continuous discharge mode of operation, has been involved for the last four years in the development of technology to effectively treat plant waste water prior to any discharge from the Climax property. To implement this program, it was essential to define the drainage system surrounding the tailing impoundment area and effectively reduce this area with a series of interceptor canals to bypass as much runoff waters around the tailing system and into the natural streams. This series of interceptors then allowed for projections of the amount of runoff waters which could not be excluded from the tailing system and would amount to an inflow quantity of water which would have to be handled on an average annual basis to maintain total system integrity. Figure 1 graphically details the Climax tailing system with interceptors.

Climax outfall water contains small concentrations of heavy metals such as molybdenum, copper, and zinc in levels of a few parts per million. These metal constituents are the result of minor metal solubilization during the molybdenite flotation process. The mill water also contains combined cyanide in concentrations of less than one part per million. This is introduced into the mill circuit in the Regrind Plant as sodium cyanide where it is used as a copper depressant.

Laboratory work on removing impurities from Climax mill outfall water was started in 1973 with the removal of molybdenum from the mill water. This work led to the operation in 1975 of the Chem-Seps continuous Counter current ion exchange (CCIX) Pilot Unit. Through 1976, an intensive effort including pilot plant tests with the Swift Lectra Clear process has been underway to develop a system to remove the remaining heavy metals and cyanide. This paper discusses the process route selected to remove molybdenum, heavy metals, and cyanide.

Table I	Effluent and Feed Analysis						
	Fe	*Mn*	*Cu*	*Zn*	*Mo*	*Cd*	*CN*
Effluent Target-mg/l	2.0	1.0	0.05	0.2	2.0	0.015	0.025
Feed Ranges-mg/l	3.0-7.0	5.0-7.0	0.025-0.16	0.20-0.40	2.0-20.0	0.015	0.2-0.5

Laboratory and Pilot Plant Development

Laboratory and pilot plant programs directed at developing Climax waste water treatment technology were divided into two major efforts. Our first objective was to remove molybdenum to levels of 2.0 parts per million Our second effort focused on removal of heavy metals and cyanide. Target effluent concentrations for the heavy metals of interest and cyanide are listed in Table I along with typical influent concentration ranges of these same contaminants.

Development of a Molybdenum Ion Exchange Recovery System

The development of ion exchange technology for the removal of molybdenum to the low concentrations of 1-2 parts per million was started in mid-1973. The test work was restricted exclusively to the weak-base amine type anion exchange resin for two reasons: 1) the molybdenum absorption capacities were greater, and 2) the resin's high affinity for the hydroxyl ion allows for effective molybdenum elution with smaller alkaline requirements. Earlier column loading tests indicated that the amine type resins had a low capacity to absorb molybdenum when the resin was in the hydroxyl form but had a much greater capacity in the bisulfate or chloride form. Sulfuric acid was selected as the regenerant not only because of its lower cost, but also to avoid contamination of the effluent water with chloride ions.

Column Upflow Loading-Acidified Feed

Because of previous work done by AMAX[1] and others,[2] it was recognized that Mo sorption is most efficient at a pH between 3.0 and 4.0. Accordingly, the feed was acidified to pH 3.5 to 4.0 before entering the column. Amberlite XE-299 was selected after comparing loading capacity of the weak-base type resins available. With Amberlite XE-299, laboratory loadings of up to 12 pounds of Mo per cubic foot of resin at a cumulative percent recovery of 90.8 were obtained.

Resin Elution

Resin molybdenum elution efficiencies in excess of 98% were obtained. A typical elution curve is shown in Figure 2.

Paper presented at a Symposium jointly sponsored by the University of Reading and the Climax Molybdenum Company.

Figure 2

Ion Exchange Pilot Plant Operation

Chem-Seps Counter Current Ion Exchange Unit (CCIX)

The final phase in the molybdenum recovery program was to decide on an operating system to translate the laboratory procedure developed to a commercial plant. The CCIX unit was selected for piloting because, when compared to a fixed bed system, it requires considerably less resin inventory, it offers operating advantages at the high flow rates to be treated, and it occupies much less space.

The water processed in the CCIX unit was primarily Robinson Pond Tailing water. The Mo level in this water at the beginning of the test period was 11 parts per million. By the end of the period due to the dilution during the spring runoff the Mo concentration had dropped to 1 part per million. It was therefore decided to "spike" the feed with sodium molybdate to the level of 20 to 25 parts per million to facilitate the collection of the data required to design a full scale plant (resin loading, cycle time, elution efficiency, and resin degradation in operation).

The resin used was Rohm and Haas XE-299, a macroreticular weakly basic anion exchange resin, with tertiary amine functional groups. Sodium hydroxide and sulfuric acid were used exclusively for resin elution and regeneration at a concentration level of approximately 50 grams per liter. A photograph of the pilot CCIX unit is shown in Figure 3. Figures 4 and 5 describe the operation of the column in the service and pulse modes respectively.

Figure 3
CCIX PILOT PLANT UNIT
Tested at Climax, Colorado

The CCIX Unit is installed within a frame of structural steel tubing 5' x 5'6" x 27' high. The column is 31'6" total height. The pulse and load chambers are made of 304 stainless while the regenerate and elution sections are of tempered glass (later many were changed to PVC). The load chamber is 12" diameter. All others are 3" *diameter.*

Figure 4

Service Mode

The fully automated system operates by continuously cycling between a "service mode" and a "pulse mode." During a service mode, the loop valves A, B, C, D, and E are closed, effectively dividing the loop into five sections: loading, regeneration, elution, pulse, and resin storage. In the resin loading chamber feed water is pumped (Valve 1) downflow through the resin bed and treated effluent is delivered (Valve 2) from the bottom of the resin loading chamber.

Sulfuric acid regenerate at 50 grams per liter is pumped (Valve 3) through eluted resin in the regenerate section between loop Valves C and E and exits (Valve 4) as a barren regenerate after sorption by the resin of the bisulfate ion. Simultaneously, sodium hydroxide eluting solution at 50 grams per liter is pumped (Valve 6) through loaded resin in the elution section between loop Valves E and B and exts (Valve 7) as a sodium molybdate solution after desorption of the molybdenum on the resin by the hydroxyl ion.

Backwash water, which enters at the base of the reservoir vessel, fluidizes the loaded resin bed and carries foreign materials and resin fines out the resin overflow line.

Following backwashing, loaded resin from the resin storage area is gravity fed through loop Valve A into the pulse section. Sonic pulse control sensors close Valve A when the pulsing section is properly filled.

Figure 5

Pulse Mode

During the pulse mode, loop Valve A is closed and loop Valve B, C, D, and E are open. Valves 1, 2, 3, 4, 5, 6, 7, 8, 9, and 11 are closed. A hydraulic pulse of water (Valve 10) and a hydraulic secondary pulse of water (Valve 2a) transfer the resin around the loop for a preselected distance. This movement puts loaded resin from the pulse vessel into the elution section, moving stripped and rinsed resin from the elution section into the regenerate section into the loading chamber, and finally moving the loaded resin from the loading chamber around to the storage area. The pulse mode takes about 30 to 45 seconds. The unit then returns to the "service mode."

Evaluation of Pilot Plant Test Run

The test series demonstrated that an average Mo concentration of 2.0 parts per million could be obtained from feed concentration ranging from 2 to 24 parts per million. Average resin loadings were 3.66 pounds Mo per cubic foot of resin.

Molybdenum resin elution efficiencies in excess of 98% were obtained. Average eluate Mo concentrations ranged between 16 and 19 grams per liter.

At a downflow rate of 41 gallons per minute per square foot the pressure drop through the resin bed was 40 pounds per square inch. This was within the allowable maximum of 50 pounds per square inch as recommended by the resin manufacturer to avoid excessive physical resin degradation. No evidence of physical resin degradation was found during the pilot plant test period. A 20% resin loss per year has been established in laboratory test work.

Tabulated pilot plant test results are presented in Tables II, III, and IV.

Sulfuric Acid	Influent pH control and resin regeneration	0.84	.75¢
Caustic	Resin Elution	0.49	2.41¢
Resin	Molybdenum removal	2.5×10^{-4} cu ft	2.50¢
		Total	7.86¢

Heavy Metals Removal

As shown in Table 1, the total amount of contaminant is quite small, however the difficulty of developing a viable process to remove that small quantity of contaminant is significant. After reviewing potentially applicable technologies, it was decided that five possible routes might yield workable processes for heavy metal removal. After running bench tests on all five options, it was clear that the only viable process was Swift's Lectro Clear system. The five technologies evaluated are reviewed below.

1. *Lime Precipitation:* Lime precipitation by itself was not successful as a potential solution due to the poor settling rates of the precipitated heavy metal hydroxides. Low water temperatures (0-4°C) and very low solids concentrations were responsible for the observed precipitate settling characteristics.
2. *Cation Exchange* — Column Loading Tests: Column loading tests showed that manganese, cadmium, and cyanide were not sorbed in any appreciable quantities.
3. *Sorption of Heavy Metals — MnO_2:* Column loading tests using a commercial grade pyrolusite (-6 +20M) as the absorbent was not effective because of early breakthrough of the heavy metals (250 gallons per cubic foot of sorbent).
4. *Ferric Hydroxide Sorption:* Increasing the amount of ferric-hydroxide via the addition of ferric sulfate prior to the lime precipitation step at a 8.6 pH showed no contribution to heavy metals or cyanide removal through physical sorption by the hydroxides, nor did it aid in solids settling.
5. *Swift Lectro Clear Process:* Positive bench scale tests and tests with a mobile trailer-mounted demonstration pilot unit at Climax during July, 1976 showed that the *Swift Lectro Clear* process held the most potential for meeting effluent requirements and thus should be tested further.

The Swift Lectro Clear process is a primary waste water treatment technique, designed to remove suspended material and/or hydroxide precipitates. After lime precipitate is conditioned in an electrocoagulation cell via contact with hydrogen and oxygen gases that are generated by electrolysis. The slurry is then mixed with a polymer flocculant and is floated in the electroflotation basin by "micro bubbles" of electrolytically generated oxygen and hydrogen and is subsequently skimmed off for disposal. The pilot unit was designed for an average flow of 10 gallons per minute and at this flow rate, residence times in the mobile unit were ten minutes in the neutralization tank, one minute in the electrocoagulation cell and 25 minutes in the electroflotation basin. Because of time limitations, the mobile pilot plant run used reagents in amounts necessary to produce a stable skim produce without attempting any optimization. Encouraging results of the preliminary trailer run led to a follow-up laboratory program to optimize reagent type and usage. During the laboratory testing program, a 10 gallon per minute pilot plant, Figure 6, was purchased from Swift and assembled in the No. 3 Mill Building at Climax. Laboratory findings were incorporated into a three month pilot plant program that culminated in an around-the-clock verification run. Table V presents performance results on the Lectro Clear system operation.

Table VI gives operating costs based on results from the continuous verification run.

Figure 6

Removal of Cyanide

There are currently many processes available for the detoxification of water cyanides. From a fundamental basis most of the commercially available methods utilize an oxidative approach to accomplish removal of both free cyanide and transition metal coordination cyanide complexes. A number of these processes have been evaluated in the context of Climax's needs and the results are summarized below.

Table V

PERFORMANCE OF LECTRO CLEAR PILOT PLANT PROCESS

Alkaline Chlorination

The alkaline chlorination process oxidizes cyanide by the addition of chlorine gas. The cyanide solution is first rendered alkaline (pH 10.5-11) and chlorine gas is injected into the process water stream. Laboratory test results, studying the effect of residence time, pH, and chlorine concentration are summarized in Table VII. Temperature was maintained at less than 10°C throughout all testing.

A confirmation test was carried out in our 10 gallons per minute Lectro Clear pilot plant at Climax. Chlorine gas was introduced directly after the lime precipitation step. Cyanide concentration was reduced from 0.14 parts per million to 0.07 parts per million with chlorine additions ranging from 5 to 50 parts per million. The low levels of 0.02 to 0.04 parts per million obtained in the lab were not reproducible in the pilot operation.

Hypochlorite Treatment

Essentially the same reactions as in alkaline chlorination result from the addition of aqueous solutions of sodium or calcium hypochlorite. The use of sodium hypochlorite has been extensively studied in the lab as well as in the pilot plant at Climax. The use of calcium hypochlorite was evaluated in the lab and performed as well as sodium hypochlorite, however, economics dictate the use of the sodium form as it can be electrolytically generated from sodium chloride solutions.

Table VIII summarizes the laboratory tests utilizing NaOCl. Feed solution was fresh No. 3 Mill water and all tests were carried out at less than 10°C.

Based on the results of these tests, a continuous verification run, utilizing the most appropriate operating conditions and reagent addition levels, was executed. In

[1]Effluent after Lectro Clear treatment for heavy metals removal

[2]Lectro Clear effluent after filtration

the pilot plant effort, the effect of pH, residence time, and NaOCl concentrations were studied. As is shown in Tables IX and X, the laboratory results were not reproduced in the Lectro Clear unit. The initial pilot plant cyanide test results were erratic with CN^- levels in the effluent varying between 0.04 and 0.08 parts per million. The average cyanide concentration in the effluent during the 66 hour run was 0.052 milligrams per liter. Also noted was that increasing the amount of hypochlorite addition did not materially affect cyanide degradation. Concentrations as high as 40 parts per million NaOCl resulted in no significant decrease in effluent cyanide levels as compared with 5 parts per million.

Although the laboratory results for cyanide degradation were not fully realized in the pilot plant circuit, the combined effects of cyanide removal in the ion exchange process and in the hypochlorite addition allowed the effluent to meet the cyanide limits.

Concurrent with the cyanide removal pilot plant testing it became evident that the heavy metal removal goals were not fully met with the Lectro Clear process. The problem centered on the requirement for a more complete elimination of precipitate. A decision was made to incorporate a high rate sand filter into the process scheme to "polish" or insure the quality of the effluent.

Tables XI and XII present a total circuit analysis including ion exchange, Lectro Clear process, oxidation, and sand filtering.

Table XII

PILOT PLANT RUN - OVERALL MATERIAL BALANCE*

*Basis: 66 hours, 2.66% solids in skim, effluent pH = 10.5, feed pH to IX column 3.5.

Conclusion

Process definition for waste water treatment at Climax incorporates counter current ion exchange for molybdenum removal, followed by Swift electrocoagulation-electroflotation for heavy metals removal with a polishing filter for final effluent clarification. Sodium hypochlorite is added prior to the electroflotation basin as an oxidant for cyanide destruction. Pilot scale operations indicate essentially all the iron and manganese and in excess of 90% of the zinc, copper, molybdenum and cyanide are removed. The molybdenum removed by the ion exchange unit will be processed by solvent extraction-crystallization producing a marketable sodium molybdate. Skim electroflotation products will be chem fixed and returned to the tailing area for impoundment. The above processes are now being incorporated into a dual 2,000 gallon per minute plant with all pilot processes included in the production facilities. Full scale operation is planned in early 1978, to treat process water prior to that year's annual snowmelt.

The success of this process development is attributable to the cooperative effort between the Climax Mill, AMAX Extractive Research Group in Golden, and the AMAX Environmental Services Group, all providing specific expertise in outlining specific goals and objectives to this complex problem. The inclusion and adaptation of the Swift Lectro Clear process to treatment of process water at Climax is, we think, a first for the mineral industry and provides a novel and exciting approach to waste water treatment in the minerals industry for the future.

Mr. Richard D. Gott holds a BS in Mining and Metallurgical Engineering from the University of Idaho, School of Mines. He became Mill Superintendent at the Climax Colorado Mill in January, 1976. He chaired the AIME Intermountain Minerals Conference at Vail, Colorado.

Mr. John M. Laferty, Jr., is Manager, Extractive Metallurgy for AMAX Extractive Research & Development, Inc., at Golden, Colorado. Prior to 1974, he was with G.T.E. Sylvania as Manager, Chemical Research and Development in Towanda, Pennsylvania. He holds a B.S. Degree in Chemical Engineering from Villanova University.

In the development of this process, special thanks are due to Paul Zundel and Gary Van Riper of the Golden Lab and, also, to John Richards, Climax, Chief Metallurgist.

Treating Tailings Waters From Moly Operations—A Review

Gopalan Ramadorai

Removing pollutants from tailings water is a prime concern at Climax's Henderson mine.

Tailings water from primary flotation concentrators usually contains minor amounts of pollutants such as heavy metals, cyanide and solubilized molybdenum, which are solubilized in the flotation process. A review of various techniques to reduce pollutants to acceptable levels is presented.

Generally, molybdenite ores are processed by conventional size-reduction techniques, followed by flotation to produce a metallurgical-grade concentrate of 88% to 92% MoS_2. Reagents commonly used in the milling process include: vapor oil (collector); pine oil, MIBC (frother); Dowfroth 250 (water-soluble frother); lime (rougher pH control); and sodium cyanide (Fe and Cu depressor). For lead depression, Nokes reagent is stage-added to the regrind mills and cleaners. Floeculant is added to obtain clear overflows in the intermediate thickeners.

What's Needed to Treat Moly Talls Waters

About 2120 L (560 gal) of water or 2.33 st are required to process one short ton of ore; if 80% recycle is practiced, the fresh water usage will be 420 L (112 gal) or 0.47 st per ton of ore processed. In areas where there are significant quantities of rainfall, bleeding a part of the tailings pond decant water prior to discharge is essential to maintain water balance.

The flotation process tends to solubilize small amounts of heavy metals such as molybdenum, copper, manganese, and zinc. Low levels of cyanide are also present in the water; this can usually be attributed to the use of sodium cyanide in the milling circuit. If clarification is inadequate, total suspended solids content in the tailings pond decant water may increase.

Most of the flotation collector normally reports into the final concentrate. The balance of the collector is adsorbed in the tailings with very little reporting in the decant water. The same comments are valid for water-insoluble frothers like MIBC and pine oil; but the amounts of frother used are significantly smaller compared to the collector level. If the tailings pond decant water is visually frothy, it is an indication that excessive levels of frother are being used. The obvious solution would be to lower frother use in the mill.

Close control of the usage of water-soluble frothers like DF 250 in the mill will alleviate visual frothing of tailings

Gopalan Ramadorai is presently Senior Research Engineer for US Borax Research Corp., Anaheim, Calif.

ponds decant water. This is also applicable to surfactants like Syntex L.

In general, pollutants that may require treatment are the heavy metals, including molybdenum and cyanide.

Treatment of tailings water is done for two reasons; minimize heavy metal pollutants so as to meet pollution control requirements, and minimize the effect of MoS_2 recovery loss upon water recycle. However, the constituents of the recycle water that contribute to MoS_2 losses in the flotation circuit are not clearly defined.

Molybdenum Reduction

The Mo level of tailings water is in the range of 2 to 4 ppm and 7 to 10 ppm Mo with water recycle. The levels after treatment will depend upon the water flow since the discharge limit is usually in pound per day. With no recycle, these concentrations are expected to be below 1.0 ppm and 2.0 ppm with the recycle. A review of the important techniques follows.

Coprecipitation with hydroxides of Al and Fe—Molybdenum can be removed from aqueous solution by sorption or coprecipitation with flocculant hydroxides of iron (III) and aluminum (III). However, the quantity of dissolved aluminum required is greater than iron. For this reason, testwork with aluminum has been limited.

The chemistry of the Mo removal process with ferric iron is fairly straightforward. The optimum pH is between 3 and 4 and the Fe/Mo ratio controls the degree of Mo removal with the residual Mo concentration dependent upon the initial[5] concentration. The Fe/Mo ratio required for optimum removal is in the range of 6 to 10.

The technology for removal of the Fe-Mo complex is more complicated. Conventional solid-liquid separation of the complex by thickening may not be practical in view of the slow settling characteristics of the Fe-Mo precipitate. The use of flotation techniques for its removal has been investigated by the USBM and the Moly Project at the University of Colorado for solid-liquid removal.[6,7]

The Bureau of Mines has investigated the technique of dissolved air flotation (DAF) for removal of the Fe-Mo complex. An Fe/Mo ratio of 6 was found to reduce the Mo level from 4.0 to 0.5 ppm on synthetic solutions. Further testwork simulating recycle liquors with higher levels of Mo is continuing.[6]

Small-scale pilot testing using a specially designed DAF unit has been conducted by Jordan and coworkers at the University of Colorado under the sponsorship of the "Molybdenum Project."[7] The overflow rates were in the range of 122 to 367 L/min per m^2 (3 to 9 gpm per sq ft). Available commercial units usually operate at lower rates of 41 to 82 L/min per m^2 (1 to 2 gpm per sq ft).

Both the USBM and Jordon et al used a surfactant like sodium lauryl or capric sulfate to promote the flotation of the Fe-Mo complex.

While the technique appears to be feasible, several problems remain, including: (1) Will the treated water meet regulations for total iron and total suspended solids levels; (2) Will there be a further need for polishing of the treated effluent by filtration techniques; and (3) What about the handling and disposal of the Fe-Mo sludge? Finally, the overall question of the process economics remains, as the technical problems are solved.

Ion exchange—The literature has many references on the chemistry of Mo removal by ion exchange techniques. The removal of Mo is most efficient in the pH range of 3.0 to 4.0; amine-type anion exchange resins are used. Weak

In moly mills, the flotation process tends to solubilize small amounts of heavy metals such as molybdenum, copper, manganese, and zinc. Low levels of cyanide are also present in the water, owing to the use of sodium cyanide in the milling circuit.

base amine types were selected by Climax due to their higher Mo absorption capacities and smaller alkaline requirements for elution. Plus, the resin in the bisulfate or chloride form had a greater capacity to load Mo compared with the free form.

Amberlite XE 299 was chosen for development work. Laboratory loadings of up to 192 kg of Mo per m^3 (12 lb per cu ft) of resin at a cumulative percent recovery of 90.8 were obtained. Resin moly elution efficiencies in excess of 98% have also been obtained.

Ion exchange on a commercial scale is performed in several ways. A brief reference to these follows:

■ Fixed Bed Downflow Ion Exchange—It is essential to present a clarified liquor as free of solids as possible to the fixed bed column. Feed liquor is clarified by filtration; if the slimes are ultra-fine, coagulation and flocculation precede filtration. When this is done, care must be exercised in the use of flocculant; an excess may be deleterious to the resin.

If algae is a problem, addition of an algicide would be recommended. If this is not done, fouling of resin will probably occur. Chlorination could also be used to destroy the algae.

■ Resin in Pulp (RIP) Process—The process was developed to handle turbid liquors by ion exchange from U_3O_8 leach liquors. High maintenance costs and excessive resin losses have made the process obsolete.

■ Chemseps Countercurrent Ion Exchange (CCIX)—Pioneered by Climax for Mo removal in tailings water, the fully automated system operates by continuous cycling between a "service" mode and a "pulse" mode. During the service mode, loading regeneration, elution, pulsing and resin storage are performed in five separate sections in a continuous loop. The resin is moved from one section to another by sonic pulsing. Backwashing removes suspended solids and fine resin.

This system attempts to minimize the problem of TSS while maintaining high flow rates; it requires less resin inventory. An average Mo concentration of 2.0 ppm could be obtained from feed concentration ranging from 2 to 24 ppm. Average resin loadings were 59 kg/m^3 (3.66 lb per ft^3) of resin.

■ Fluid Bed Ion Exchange—Several designs have been described in the literature, including the Cloete and Streat, the USBM design by Rosenberg and Ross, Ritchey et al, Haines et al,[18] and the Himsley Contactor.[9] All of these have potential application in moly removal from wastewater streams.

Removal of Heavy Metals

The effluent guidelines are noted in Table 1. Data on Climax are found in Reference 2; information on other operations is not generally available. The levels of heavy metals in the feed will vary depending on the degree of recycle and the solubilities of the different metals in the tailings waters. The heavy metals to be found in molybdenum milling water are usually inorganic in nature.

The chemistry of the removal of heavy metals from process wastewater has been reviewed.[20] Technology available for heavy-metal removal is varied; e.g., the chemical precipitation of heavy metals by pH adjustment followed by flocculation and clarification, activated carbon adsorption, reverse osmosis, ion exchange, and cementation.[2] Conventional lime precipitation is not generally useful due to the poor settling nature of the metal hydroxides. The solids content is also low due to the relatively low levels of pollutants in the recycled water. Cation exchange does not appear to be feasible, as noted by Climax.[2] Cementation is not generally applicable since it is done in acid solutions.

Table 1—Effluent Guidelines for the Ferroalloy Ore Mining and Dressing Industry

	Effluent 24 hr. (max.*)	Effluent 30 day (average*)
F-	3.0	—
T. Fe	0.6	—
Mn	1.0	1.0
As	1.0	0.5
Cu	0.1	0.05
Mo	2.0	1.0
Zn	0.2	0.10
Cd	0.10	0.05
CN	0.04	0.02
TSS	30.00	30.00
pH	6-9	6-9
COD	50.0	25.0

* All values in mg/L except pH.

In addition, the more active metal used as the cementing agent will dissolve in the process and may need to be removed. Reverse osmosis as noted by Lenouette[21] is still in the development stages.

The use of ferric chloride or sulfate as a coagulant followed by lime to pH 8.6 was attempted by Climax with little success;[2] solids settling was not improved.

Several flotation techniques are available. These include Dissolved Air Flotation (DAF), Induced Air Flotation (IAF) and the Swift Lectroclear process.

Dissolved air flotation (DAF)—Primarily used in the removal of oils and grease from industrial wastewaters, the process saturates wastewater under air pressure. When the pressure is reduced, excess air is released, forming bubbles of 30 to 120 microns in diameter. These bubbles attach themselves to the suspended matter or oil and are floated to the top of the flotation basis since the average density of the aggregates is less than that of water. Chemical coagulants and flocculants are usually added to ensure good separation. The DAF process as a means of heavy metals removal (except molybdenum) does not appear to have been evaluated.

Induced Air Flotation—The IAF system operates on the same principle as the pressurized DAF units with one difference; the gas is self-induced by a rotor-dispersed mechanism, and is dispersed in the water.

Swift Lectroclear Process—The process is applicable for solid-liquid separation when the total suspended solids (TSS) is below 8000 mg/L. It is especially valuable in separating solids which are easily destabilized by electrodes.[22] In the Swift process, the heavy metals are precipitated as hydroxides into lime. The hydroxide precipitate is electrolyzed in an electrocoagulation cell. Hydrogen and oxygen are produced in the process. These attach themselves to the slurry and render them lighter than water. Subsequently, a polymer flocculant is added to agglomerate the precipitate, which is then floated off in the electroflotation basin by electrolytically generated oxygen and hydrogen. The skim containing the hydroxides of the heavy metals and excess lime is disposed of, while the effluent from the cation removal process has to be filtered in a high-rate sand filter to remove the residual TSS.

Gott[2] has reported optimum results in the removal of heavy metals with the Lectroclear process at a pH of 10.5 on mine tailings wastewater at Climax, Colo.

Treating Cyanide

Several treatment techniques are available to lower cyanide to the target level of 0.02 mg/L.[24] The feed cyanide level can range from a low of 0.02 to a high of 0.50 mg/L. Chemical oxidation by alkaline chlorination is appropriate for these levels. The oxidant can be chlorine gas, sodium

hypochlorite or calcium hypochlorite; cyanide is rapidly oxidized to cyanate. Retention times for oxidation are in the range of 0.5 to 2.0 hr; a pH of 10 or higher is necessary. Additional chlorine can be used to oxidize the cyanate further to nitrogen and carbon dioxide or to carbon dioxide and ammonia by acid hydrolysis at a pH of 2 to 3. This requires readjustment of treated water to a pH range of 6 to 9 prior to discharge.

Alternatively, excess chlorine can be added at pH 8 to 8.5 to oxidize the cyanate to nitrogen and carbon dioxide; retention time of 1 hr is essential. Excess chlorine is needed to prevent the formation of highly toxic cyanogen chloride.

Hydrogen peroxide plus formaldehyde has been used by DuPont in their Kastone process to oxidize cyanide to cyanate.[25] The major disadvantage of the process is its inability to oxidize cyanide below the level of cyanate. However, if the cyanide is present as "free" cyanide and not complexed, the process could be attractive since no problems of cyanogen chloride are encountered.

Hydrogen peroxide alone will probably by equally effective in lowering cyanide levels. The same comments on "free cyanide" will apply to this as those stated above for the Kastone process.

Climax has used hypochlorite in lowering cyanide to acceptable levels on the effluent from the Chemseps Ion Exchange unit used for lowering Mo levels in tailings water.[3]

Fluoride

Several approaches are possible; choice of a specific process depends on the effluent.[26,27]

The most widely used treatment consists of the addition of a soluble calcium salt to form insoluble calcium fluoride which is removed by liquid-solids separation. The optimum pH for precipitation is between 8 and 9. The fluoride levels after treatment vary from the theoretical solubility limit of 7.8 mg/L to about 30 mg/L. For lowering the fluoride levels even further, the most promising treatments are alum precipitation and adsorption on activated alumina.

Alum (aluminum sulfate) has been used to lower fluoride levels in potable waters in the pH range of 6.5 to 7.5. The quantity of alum needed depends on the initial fluoride level and the desired final level; this increases as the residual fluoride level decreases. Extensive amounts of sludge are produced in the process; settled sludge will amount to 18% to 40% of the volume treated.[28]

Activated alumina can reduce fluoride ion levels to less than 2 mg/L. Problems of handling regenerant and the effect of regenerant on overall effluent quality are yet to be resolved.[28]

In general it can be said that technology for fluoride reduction to low concentrations is not well established. An extensive development program will be essential to determine the applicability of the defluoridation techniques discussed earlier to the effluent in question. □

[57] **ABSTRACT**

A process for removal of heavy metals in their anionic state, particularly tungsten and molybdenum, from industrial mining wastewater by chemical precipitation of the heavy metal values, followed by gas flotation.

10 Claims, No Drawings

PROCESS FOR RECOVERING MOLYBDENUM AND TUNGSTEN FROM MINING WASTEWATER

This invention relates to the recovery of heavy metal values from mining wastewater, and more particularly, to the recovery of heavy metals such as tungsten and molybdenum which are present in their anionic state, by forming insoluble precipitates of these values and thereafter removing same by gas flotation.

Formerly, heavy metal values were removed from mining wastewater only if they were present in sufficient amounts that their recovery would enable sale for profit. However, more recently, in view of Environmental Protection Agency standards directed to the composition of industrial discharge waters, it has become necessary to treat various industrial wastewaters to obtain a discharge water composition having low levels of heavy metals. Accordingly, it has become necessary to devise an efficient, inexpensive method of treating mining wastewaters to minimize their content of heavy metals.

One such process which has been used in the past consists of an ion exchange process wherein heavy metal values, such as molybdenum and tungsten, are replaced with other anions in an ion exchange bed. A second prior art process entails treating mining wastewaters by reverse osmosis wherein wastewater is subjected to high pressures (about 100 psi) and the wastewater is selectively passed through a semi-permeable membrane to separate the heavy metal values from the remaining wastewater. Both the ion exchange process and the reverse osmosis process require very expensive capital installations and high operating costs. Accordingly, such processes are not feasible when applied to removing relatively small quantities of heavy metal values from wastewater, e.g. 20 ppm.

Another general concept for removal of heavy metal values from wastewater comprises forming heavy metal precipitates, and thereafter removing such precipitates from the wastewater. Removal is generally effected by allowing the precipitates to settle out. This means of separation is very inefficient. The present invention, on the other hand, involves a unique and surprising process for efficiently and inexpensively removing heavy metal values.

It is an important object of the present invention to provide an improved process for treating wastewaters to remove heavy metal values.

It is an additional object of the present invention to provide an improved process for treating mining wastewaters to remove molybdenum and tungsten values.

It is also an object of the present invention to provide an improved process for forming insoluble complexes of molybdenum and tungsten within the wastewaters, and thereafter removing such complexes by gas flotation.

It is a further object of the present invention to form insoluble tungsten and molybdenum complexes in mining wastewater, and thereafter removing such complexes by flotation with electrolytically generated microbubbles.

Generally, the objects of the present invention are carried out by a selective precipitation of anionic metal complexes within a narrow pH range of between about 2.0 and 6.0, followed by gas flotation. The process is amenable to any aqueous medium containing heavy metal values in their anionic form, but is primarily directed to the treatment of mining wastewater, such as

mine water tailings, that contain trace amounts of heavy metals. Heavy metals that may be removed include tungsten (as tungstates), molybdenum (as molybdates), chromium (as chromates) and arsenic (as arsenates).

Initially, the pH of the mining wastewater is adjusted to a value of between 2.0 to 6.0, and preferably between 3.0 and 5.0. This is accomplished by the addition of a mineral acid to the wastewater in sufficient amounts to provide the desired pH. Although any mineral acid may be utilized to adjust pH, it is preferred to use sulfuric acid in view of its availability and low cost.

Also, a trivalent metal cation is added to the wastewater, either before or after pH adjustment. The trivalent metal ion may be ferric, cobalt, aluminum, chromium or rhodium. Preferably, however, ferric sulfate is used to provide trivalent ferric ions in view of its availability, low cost, and ease of use. The trivalent metal cation is added to the wastewater in amounts so as to provide from about 6 to 20 parts per million (ppm) of the trivalent metal cation to each ppm of the heavy metal ion, and preferably, from 8 to 12 ppm of the trivalent metal cation to each ppm of the heavy metal ion. One part per million (1 ppm) is equivalent to one milligram per liter. The treated wastewater is then preferably retained for at least 3 minutes prior to any further processing, so as to enable the formation of insoluble ferric molybdate, tungstate, chromate and arsenate salts.

After retention, a basic chemical is added to the wastewater in order to provide hydroxyl ions to form insoluble ferric hydroxide with the excess ferric ions. Any source of hydroxyl ions is suitable, but preferably, calcium hydroxide (lime) is used. The base should be added in an amount to raise the pH slightly, but not in excess of pH 6. Preferably, the base will be added in an amount to increase pH about 0.5 units above the pH obtained subsequent to acid addition. The hydroxyl ions will form, at acidic pH, a gelatinous precipitate with aluminum as well as ferric ions. Apparently, the gelatinous ferric hydroxide co-precipitates with the insoluble heavy metal salts.

After treatment of the mining wastewater in accordance with the above-described procedures, the wastewater stream is subjected to a dense flow of gas bubbles to create embryo flocs of heteropoly molybdate and tungstate salts as well as metal hydroxides. The dense zone of bubbles may be supplied by a source of dispersed gas or dissolved gas (such as pressurized air). Preferably, however, the dense zone of very fine microbubbles is generated electrolytically, usually by decomposition of the wastewater. Generally, the wastewater flow is horizontal while the gas bubbles initially contact the wastewater flow in a substantially vertical orientation. It has been found that the microbubbles for flotation are most effective when exhibiting diameters of 10–500 microns, preferably 20–300 microns, and most preferably 30–150 microns. Moreover, the bubbles should be generated in sufficient quantity to provide from 10^4–10^9 bubbles per liter of wastewater treated, and preferably from about 10^6–10^8 bubbles per liter of wastewater treated. Also, the microbubbles should comprise from 0.1 to 10.0 volume % of the wastewater being treated.

As previously mentioned, the dense zone of bubbles is preferably generated electrolytically. This may be carried out by passing the wastewater stream through an electrocoagulation cell which contains an electrode grid positioned horizontally just above the bottom of

the cell. This electrode grid will consist of appropriately spaced pairs of anodes and cathodes to provide a suitable current density across the bottom of the cell to generate the desired volume of microbubbles. Depending on the density and volume of microbubbles to be generated, the electrode grid is generally designed to provide an energy input of between about 0.5 to 20 ampere-minutes per gallon of wastewater treated, and preferably from about 5 to 10 ampere-minutes per gallon. Design of the electrode grid arrangement should be in accordance with U.S. Pat. No. 3,959,131 of Ramirez et al., the description of which is incorporated herein by reference.

Treatment of the wastewater stream with a dense zone of gas microbubbles causes insoluble molybdate and tungstate complexes to agglomerate together in embryo flocs, buoyed upwardly by the rising microbubbles. These embryo flocs could be allowed to collect at the surface, and could then be removed as by skimming. However, it is greatly preferred to add a polyelectrolyte polymer flocculent to the embryo floc-containing wastewater at this point, and then flowing the wastewater into a basin where it is subjected to a second flotation with gas microbubbles. The flocculant can be any high molecular weight polyelectrolyte polymer normally used to floc particulates, but preferably it will be an anionic polyacrylic acrylamide, usually in amounts of from about 0.5 to 6 ppm (mg/L).

Microbubbles in the basin can be generated by means of dispersed gas, dissolved gas, or preferably, may be generated electrolytically. When electrolytic microbubble generation is contemplated, the wastewater may be flowed into a large, open rectangular basin having an electrode grid horizontally positioned across the bottom. Preferably, this electrode grid will extend over only a portion of the length of the basin, and will be designed to provide a decreasing density of microbubbles along the length of the basin from influent end towards effluent end. To effect gradient current density zones, and thus gradient bubble density zones, grids may be designed in accordance with the disclosures in U.S. Pat. Nos. 3,959,131 of Ramirez et al. and 4,012,319 of Ramirez, the descriptions of which are hereby incorporated by reference.

The microbubbles generated in the flotation basin act to promote further floccing of the embryo flocs, resulting in full-grow flocs that are buoyed to the surface of the basin. These full flocs may then be skimmed from the surface, as with countercurrent directed skimmer blades positioned above the basin, and treated to remove molybdenum and tungsten values. Generally, the present invention is operable to reduce total Mo and W values down to levels of less than 1 ppm, and often as low as 0.3 ppm. Also, total iron content is reduced due to the formation of insoluble ferric hydroxide. Moreover, the present invention is operable to treat relatively large volumes of wastewater in the range of up to several thousand gallons per minute.

Another advantage of the present invention is that it may be carried out utilizing relatively low capital equipment costs. In addition, chemicals normally used to form the insoluble heteropoly heavy metal precipitates are sulfuric acid and ferric sulfate, both of which are inexpensive and readily available. Finally, in addition to providing a wastewater suitable for discharge in accordance with EPA regulations, heavy metals, such as tungsten and molybdenum, in the skimmings are readily recoverable for their market value.

While we are not positive as to how the insoluble heteropoly heavy metal complexes are formed in accordance with the present invention, it is believed that with respect to molybdenum, the following reactions take place. It is hypothesized that in an acidic solution with a pH of between 2.0 and 6, the addition of ferric sulfate salt to the wastewater stream results in the formation of the ferric salt $(Fe_2Mo_4O_{24})^{-6}$. It is further believed that this ferric salt, when in the presence of excess ferric ion, is subsequently converted to the ferric heteropoly molybdate salt $Fe_2(Fe_2Mo_4O_{24})$. We also believe that pH control is especially critical in carrying out the present invention because at pH values in excess of about 5 or 6, ferric hydroxide becomes less soluble than the ferric heteropoly molybdate, and therefore, the ferric ion is depleted by forming ferric hydroxides, and so becomes unavailable to form the insoluble heteropoly molybdate salt.

The following examples are intended to set forth illustrative embodiments of the process and are not to be taken in any manner as limiting the scope of the invention as defined by the appended claims.

EXAMPLE I

A molybdenum processing wastewater exhibited the following metal components: 1.6 ppm molybdenum, 2.0 ppm iron. The pH of the wastewater was 6.8. The wastewater was treated with 400 ppm of sulfuric acid to adjust pH to a value of 2.0. Thereafter, ferric sulfate in an amount sufficient to provide 19 ppm of ferric ion per ppm molybdenum ion was added to the wastewater. Subsequently, 100 ppm calcium hydroxide was added. The wastewater was then treated with four (4) ampere minutes of electrical energy per gallon within an electrolytic cell so as to form embryo flocs of ferric heteropoly molybdate salts and ferric hydroxide. Thereafter, 2 ppm of anionic polymer flocculant was added to the wastewater, which was then subjected to an additional four (4) ampere minutes of electrical energy per gallon such that the entire floc of ferric molybdate salt and ferric hydroxide was floated to the surface by gas buoying. Analysis of the resulting treated water showed molybdenum values at 0.33 ppm and total iron values of 0.5 ppm.

EXAMPLE II

A molybdenum processing wastewater was doped to contain 18 ppm Mo and 1.5 ppm iron. 216 ppm of ferric ion was added as ferric sulfate, and pH was adjusted to 2.0 by addition of 100 ppm sulfuric acid. 200 ppm lime was then added to raise pH to 4.5. The solution was then treated in an electrocoagulation cell with 5 ampere-minutes current per gallon. 4 ppm of an anionic polymer flocculant was added and thoroughly mixed. The solution was then treated with an additional 3 ampere-minutes of electrical energy per gallon, causing flotation of the ferric molybdate salt and ferric hydroxide. Analysis of the treated solution showed the presence of Mo at 0.35 ppm and total iron at 0.6 ppm.

EXAMPLE III

Mine tailing effluent containing 1.86 ppm molybdenum was treated by this process. Ratio of ferric sulfate added was either 6 ppm ferric to 1 ppm molybdenum or 12 ppm ferric to 1 ppm molybdenum. Initial pH adjustment was made by addition of from 120–760 ppm sulfuric acid, giving a solution pH of from 2.0 to 3.09. A second pH adjustment was made by addition of from 0

to 120 ppm lime, giving a final pH of from 2.0 to 10.8. The precipitates formed were coagulated with electrolytically generated microbubbles, after which 3 ppm of anionic polymer was added. Additional electrolytically generated microbubbles were utilized in effecting flotation of the coagulated precipitate. Flotation skimmings were removed, and the remaining solutions were analyzed for molybdenum. Results were as follows:

Initial Conc. of Mo	Ratio Fe/Mo (ppm)	ppm H_2SO_4/pH	ppm Lime/pH	Final Conc. of Mo	% Removal
1.86 ppm	6:1	700 (2.0)	0 (2.0)	1.9 Mo ppm	0
"	6:1	140 (3.0)	0 (3.0)	1.9 Mo	0
"	6:1	140 (3.0)	25 (3.65)	0.94 Mo	54.8
"	6:1	140 (3.0)	40 (4.34)	1.0 Mo	46.2
"	6:1	140 (3.0)	80 (6.30)	1.6 Mo	14.0
"	6:1	140 (3.0)	120 (9.83)	1.7 Mo	8.6
"	12:1	100 (3.14)	0 (3.14)	1.3 Mo	30.1
"	12:1	110 (3.03)	25 (3.58)	0.58 Mo	68.8
"	12:1	120 (3.02)	40 (4.00)	0.24 Mo	87.1
"	12:1	120 (3.05)	80 (5.80)	0.54 Mo	71.0
"	12:1	120 (3.03)	90 (6.26)	0.72 Mo	61.3
"	12:1	120 (3.09)	120 (10.8)	1.56 Mo	16.1

EXAMPLE IV

Synthetic "doped" solutions were prepared containing either 20 ppm molybdenum, 20 ppm chromium or 20 ppm tungsten. The ratio of ferric ion to Mo, Cr or W was either 6:1 or 12:1. Initial pH was adjusted by addition of sulfuric acid, with pH being subsequently adjusted by addition of lime. As in Example III, the solutions were treated with electrolytically generated microbubbles, anionic polymer added, and again treated with microbubbles. Flotation skimmings were removed and final solutions analyzed for Mo, Cr or W. The results were as follows:

Initial Conc. of Mo, Cr or W	Ratio of Fe to Mo, Cr or W	ppm H_2SO_4 and pH	ppm Lime and pH	Final Conc. (ppm)	% Removal
20 Mo ppm	6:1	200 (3.08)	40 (3.58)	1.27 Mo	93.6
"	6:1	200 (3.02)	80 (4.30)	1.32 Mo	93.4
"	6:1	200 (2.99)	100 (5.35)	1.46 Mo	92.7
"	6:1	200 (3.09)	250 (8.25)	12.0 Mo	40.0
"	12:1	60 (2.97)	60 (3.30)	0.57 Mo	97.2
"	12:1	60 (3.00)	100 (4.42)	0.56 Mo	97.1
"	12:1	60 (3.30)	250 (8.41)	9.4 Mo	53.0
"	12:1	40 (4.30)	280 (9.05)	10.7 Mo	46.5
20 Cr ppm	12:1	60 (3.02)	100 (4.55)	10.0 Cr	50.0
20 W ppm	12:1	100 (2.70)	100 (4.30)	5.0 W	75

Obviously, many modifications and variations of the invention as hereinbefore set forth may be made without departing from the spirit and scope thereof, and only such limitations should be imposed as are indicated in the appended claims.

We claim:

1. A method for removing heavy metals selected from the group consisting essentially of molybdenum, tungsten, chromium and arsenic from wastewater in their anionic forms as molybdates, tungstates, chromates and arsenates comprising the steps of adding to a wastewater having a pH of between about 2.0 to 6.0, a trivalent metal ion selected from the group consisting of ferric, cobalt, aluminum, chromium or rhenium to the wastewater in an amount sufficient to provide from 6 to 20 ppm trivalent metal cations per ppm of total molybdate, tungstate, chromate and arsenate ions to form insoluble heteropoly molybdate, tungstate, chromate and arsenate salts within the wastewater; adding a hydroxyl providing base to raise the pH yet maintain it within the acidic range to form a gelatinous precipitate; subjecting the wastewater to a dense zone of microbubbles to form embryo flocs from the insoluble salts; adding an anionic polyelectrolyte polymer flocculant to the wastewater; and thereafter subjecting the wastewater to an additional dense zone of microbubbles to form from the embryo flocs full flocs that are buoyed to the surface.

2. The method of claim 1 wherein the microbubbles are electrolytically generated in an amount of from 10^4–10^9 microbubbles per liter of wastewater and comprise from 0.1 to 10 volume % of the wastewater being treated.

3. The method of claim 2 wherein the microbubbles exhibit a diameter of from 20–300 microns and wherein the bubbles are provided in amounts of from 10^4–10^8 per liter of wastewater.

4. The method of claim 2 wherein the pH of the wastewater is initially adjusted to from about 3.0 to 5.0 and wherein from about 8 to 12 ppm of trivalent metal ion per heavy metal ion is added.

5. The method of claim 2 wherein the trivalent metal ion is ferric ion supplied by ferric sulfate.

6. The method of claim 2 wherein the flocculant is an anionic polyacrylic acrylamide and is added in the amount of 0.5 to 6 ppm.

7. The method of claim 2 wherein the second dense zone of microbubbles to which the wastewater is subjected exhibits a decreasing density of microbubbles from the influent end toward the effluent end of the zone.

8. The method of claim 2 wherein the wastewater is mining wastewater.

9. The method of claim 2 wherein the hydroxyl providing base is calcium hydroxide.

10. The method of claim 2 wherein the initial pH is adjusted by addition of sulfuric acid.

* * * * *

McDOUGALL (1984, personal communication) has tested and possibly patented a process whereby molybdenum is removed from acidic solutions by adsorption on activated carbon. By simply modifying the pH, molybdenum oxide-hydroxide can be either in an uncharged polymeric form, or the polymer can be depolymerised releasing molybdenum back into anionic form. Since the uncharged polymer adsorbs readily onto activated charcoal while charged ionic species do not adsorb well, carbon's affinity for molybdenum can be controlled.

A similar observation concerning fouling of ion exchange resins by molybdenum polymers was made at a New Mexico in situ leach test at Nose Rock by BATEMAN URANIUM CORP. Anton R. Hendricksz, now of BECHTEL CORP., and Wayne C. Henderson of KENNECOTT MINERALS CORP., Salt Lake City, would be familiar with this phenomenon.

No commercial scale application of carbon adsorption for molybdenum removal from effluents is known to be in current operation.

ION EXCHANGE

As mentioned above by GOTT and LAFERTY (1977) and RAMADORAI (1978), ion exchange is an effective way to remove molybdenum from acidic solutions. The process works best around pH 3.8, and there are several ion exchange systems to choose from, notably NIMCIX from MINTEK, South Africa, the PORTER System, HIMSLEY System, and CHENSEPS, INC. plugflow system.

When considering installation of such a system, some conservatism is in order in the sizing of commercial-scale CHEMSEPS units as in the past these seem perhaps to have been somewhat ambitious.

At CLIMAX MOLYBDENUM's water treatment plant, molybdenum was first recovered by a counter-current CHEMSEPS anion exchange system. This was followed by heavy metal precipitation and removal of the precipitate by dissolved air flotation followed by cyanide destruction using chlorine at pH 10.5-11.0.

COAGULATION WITH IRON

RAMIREZ (1981) described a process whereby molybdenum and arsenic were removed from a uranium tailings wastewater by electrocoagulation in which $Fe_3(FeMo_6O_{24})$ was precipitated by the addition of $Fe_2(SO_4)_3$ at pH 3.5-4.5 maintaining a Fe/Mo ratio of 10. The precipitate was skimmed from a flotation cell for Mo recovery and iron recycling. In the laboratory, W and Cr were also removed by the process. This process formed the

basis for the RAMIREZ and RAMADORAI (1980) patent for molybdenum and tungsten removal from mining wastewater.

In 1981, Ernest Ramirez was emloyed at AMERICAN STANDARD, INC. Wayne, New Jersey, and in 1985 Gopalan Ramadorai was completing his contract at AMAX R&D, Inc., Golden, Colorado, and could be reached at:

GOPALAN RAMADORAI
17837 West Lunnenhaus Drive, #5
Golden, CO 80401
(303) 279-7636

It is believed that dissolved air flotation would work as effectively as the DRAVO Lectroclear Process for the removal of the precipitate after coagulation. In the case of some western U.S.A. operations which are at high altitude and hence in a cold climate, coagulation kinetics are of importance.

GEOCHEMICAL ADSORPTION

KATZ and RUNNELLS (1974) of the University of Colorado showed that soils with higher pH values with correspondingly lower amounts of organic matter and lower extractable Al levels are much less effective in removing Mo from mill solutions than acidic soils containing higher amounts of organic matter or soils containing oxyhydroxides. They pointed out that mill effluents containing Mo enter and percolate through the soil environment to contaminate groundwater reservoirs. KATZ and RUNNELS examined the ability of soils to remove Mo from infiltrating solutions. The maximum adsorption capacity of soil for Mo was 9.5 mg/g soil by desert soils and 50 mg/g Mo by agricultural soil. Alpine soils, however, showed an average sorption value of 160 mg Mo/g soil. The mountain soils had significantly higher extractable Al levels. Low soil pH values (5-6) with a higher percentage (10-14%) organic matter were also a characteristic of alpine soils. Desert and agricultural soils had almost no organic matter and had a high pH (7.8-8.2). KATZ and RUNNELLS concluded that acidic mountain soils offer far more protection to groundwater than do alkaline desert and agricultural soils.

Once again, the characteristic polymerization of molybdenum at lower pH may play a role in its mobility.

REMOVAL OF SELECTED INORGANIC POLLUTANTS FROM URANIUM MINE WASTE WATER BY BIOLOGICAL METHODS

J.A. Brierley, C.L. Brierley, and K.T. Dreher

Department of Biology, and New Mexico Bureau of Mines and Mineral Resources, New Mexico Institute of Mining and Technology, Socorro, NM USA

ABSTRACT

Water from underground uranium mines located in the Ambrosia Lake district near Grants, New Mexico, U.S.A., is treated to reduce levels of uranium, selenium, radium and molybdenum. The treatment system consists of a series of ponds and an ion exchange plant. Bacterial and algal populations present in the pond system are considered agents which actively assist in removal of the pollutants present in the water. Pond-bottom sediments maintain a reducing zone and a large population of sulfate-reducing bacteria of the genera Desulfovibrio and Desulfotomaculum. Uranium, molybdenum, and selenium accumulate in the pond sediment. Stimulation of the microbial sulfate-reducing activity resulted in a decrease of soluble concentrations of these elements in laboratory systems. Predominant components of the treatment ponds' algal flora are the filamentous Spirogyra and benthic Chara. Laboratory study indicates that Spirogyra is more active than Chara in removal of uranium and molybdenum from solution. However field-collected algal samples of both of the genera contain uranium and molybdenum. Laboratory studies indicate that death and decay of the algae in association with pond sediment does not result in return of cell-bound uranium and molybdenum to the water. The algae appear to act as bio-filters for accumulation of particulate pollutants and agents for adsorption and/or absorption of soluble pollutants.

INTRODUCTION

The mining of uranium ore may produce water from de-watering operations containing dilute concentrations of uranium, molybdenum, selenium, radium and other associated ions. This water presents a waste disposal problem, as the contaminants must be removed before the water can be discharged from a mining property. In addition, it is a potentially valuable source of economically important elements. Reclamation of mine wastewater can serve two purposes: removal of potential pollutants and concentration of resources. Several processes are available for soluble ion concentration including precipitation, ion exchange, solvent extraction and electrowinning. However, these systems are quite often ion specific and expensive when treating large volumes of water. An alternative system for resources concentration is based upon biological processes. Such a system has the potential for low cost, ion non-speci-

Lubricants, cutting oils, hydraulic fluids, fuel, reagents and surfactants, sewage and treated sewage, fats from mine hostel kitchens, and runoff from new asphalt surfaces and even decaying vegetation all introduce organics into the operational environment. Industrial activity located near a mine-mill water supply can add organics which can interfere with recovery as has been observed recently on the Witwatersrand. In this case, an abattoir effluent is discharged into a stream from which a flotation/CIP plant draws its water or, more correctly, formerly drew its water. It is doubtful if there is a single mill operator who does not believe that organics can have a significant impact on metallurgical processes. Yet, when it comes to asking ourselves how much organics and which organic species are present and what their individual effects are on metallurgical results, then one usually draws a bank. In many cases, operators are oblivious to the presence of organic species in their effluent and process water. Yet, even in very remote locations far from the nearest industry, organics can be introduced as natural hydrocarbons in the ore or as humic and fumic acids generated from decaying vegetation or perhaps as end products from decrepitating bacterial biomass, etc. Recent Landsat applications have identified hydrocarbons leaking to the surface of the earth. Such leakages would represent serious organics contamination of ore which would not be obvious to an operator working at a plant that treats it.

Once aware of the possibility that organic contaminants may have an effect on plant performance, it remains to find a way of measuring the level of contamination, determine the cost of its effect, either find and curtail the source, find a way of treating the water, or find another means of overcoming the problem.

A basic conclusion of this investigation is that when it comes to organics in mine-mill water, knowledge and insight is lacking. Further investigation and R&D are needed:

- Detection and identification of organic species in water and/or ore pulps.
- Determination (quantitative, if possible) of the effect of organic species on mining, metallurgical, and mineral processing operations.
- Development of ways to keep organics out of mine-mill waters.
- Development of cost-effective treatment technologies to remove organics from mine-mill water.

POSSIBLE SOURCES OF ORGANIC SPECIES IN MINE-MILL SOLUTIONS

Organics in mine-mill water can be derived from a surprising number of sources; these include:

- Lubricating Oils Used Underground
  - Vehicle Leaks, Mechanical Equipment
  - Poor Housekeeping in u/g Maintenance Shops
  - Use of Mine Tailings as Dumps by Industry
- Diesel Fuel Leaks
- Hydraulic Fluid
  - Line Breakages
  - Maintenance/Repair Shops
- Compressor Oil
- Cutting and Grinding Oils
- Soaps, Fats, and Waxes from Industry and Mine Hostels
- Natural Hydrocarbon Seeps
- Industrial Contaminants, e.g., Abattoirs and Oil Refiners
- SX Reagents
- Phenol from Explosives and Mineral Flotation Reagent Degradation
- SulfoLignate Dust Control Reagents and Lignins from Rotting Underground Timbers
- Sewage (Raw or Treated)

It is of interest, ONTARIO (1979), that industrial and sewage effluent discharge of oil to the Great Lakes has been estimated at 64,000 tons per year which is the equivalent to several tanker wrecks per year. Depending on location relative to industry centers, lake and river water may itself contain enough organic contaminants to be a possible factor in metallurgical efficiency. Fortunately, mines and mills are more often than not located at remote sites where this is not a problem.

A potential source of groundwater contamination by organics is through the development of leaks in underground fuel and solvent storage tanks. These can result in costly losses of fuel or solvent in addition to groundwater contamination.

ENVIRONMENTAL SENSITIVITY TO HYDROCARBONS AND PHENOLS

ONTARIO (1979) has set an objective of 1 microgram phenol/l in waters (i.e., 1 ppb) phenol to protect against the tainting of edible fish.

ONTARIO (1979) estimated "safe" levels of various hydrocarbon oils for fish as follows:

Bunker Oil	180 ul/l (ppm)
Used Crankcase Oil	120 ul/l
Crude Oil Slicks	45 ul/l
Jet Aviation Fuel	45 ul/l
Diesel Oil	15 ul/l
Automobile Gasoline	9 ul/l

INTRODUCTION

The presence and effect of organic species on metallurgical performance must surely be one of the least understood aspects of metallurgical and mineral processing operations. In this report, metal contaminants have been discussed one by one. The number of different organic species in modern industry is a large multiple of the number of inorganic species, and yet we know so little about them that all organics are lumped together in one brief section for a cursory discussion.

The above levels are higher than those that would be expected to cause problems of odor and aesthetics. ONTARIO (1979) has set the following objective for oil and petrochemicals which should not be present in concentrations that:

-- can be detected as a visible film, sheen, or discoloration on the surface;
-- can be detected by odor;
-- can form deposits on shorelines and bottom sediments detectable by sight or odor or are deleterous to resident aquatic organisms.

McKEE and WOLF (1963), following a review of world literature, concluded that phenol in a concentration of 1 ug/l phenol would not interfere with domestic water supplies, 200 ug/l would not interfere with fish and aquatic life; 50 mg/l would not interfere with irrigation; and 1,000 mg/l would not interfere with stock watering although this author for one would not be eager to eat beef watered with 0.1% phenol.

HAWLEY (1977) reviewed the use and toxicity of a wide range of mine-mill reagents in the province of Ontario which provides some insight into the environmental sensitivity of a wide range of organic reagents. This document, which is too extensive to be summarized here, is available from:

JOHN R. HAWLEY
Head, Mining, Metallurgy, and Inorganic
Chemistry Unit
Quality Protection Section
Water Resources Branch
Ontario Ministry of the Environment
1-4 St. Clair Avenue West
Toronto, Ontario

DAVIS, et al. (1976) reviewed the environmental problems of flotation reagents in mineral processing plant tailings water.

REGULATORY LIMITS ON OIL, GREASE, AND ORGANICS IN MINE-MILL EFFLUENTS

Organic substances currently are generally not listed on mine-mill operating permits. The Colorado Dept. of Health - Water Quality Control Division, which polices mine-mill effluents, currently does not test effluents for organic constituents, oils, or greases, although the U.S. EPA recently fined one Colorado operator for spilling PCB from a transformer.

During the course of this investigation, the only cases where organics were found to be included in mine-mill permits or regional/national effluent permits were:

	Maximum Average 30d	Maximum 24-Hour Average	ORGANICS Maximum Grab Sample
Con Mine, N.W.T., Oil/Grease	-	-	5.0 ppm
South Africa Proposed New Regulation for Witwatersrand Phenolic Compounds	-	-	0.1 ppm
South Africa SABS Public Water Supply, Odor/Taste	-	-	Not Objectionable

The California Regional Water Quality Control Board - Central Valley Region NPDES No. CA0081477 waste discharge requirements for the McLaughlin Mine, HOMESTAKE MINING COMPANY, permit merely states:

> "...the discharge shall not cause visible oil, grease, scum, foam, floating, or suspended material in the receiving waters or watercourses."

EFFECTS OF ORGANICS ON MINE-MILL PERFORMANCE

VIVIERS (1980) reviewed several cases where organic contaminants in recycled water interfered with mineral flotation processes and included a short literature survey. Even small amounts of some organic contaminants can have a significant impact on metallurgical efficiency or could result in environmental impacts that have to be taken into account. For example:

1) Ion exchange was selected over solvent extraction for uranium at the Agnew Lake Mine in Canada because of environmental objections to small amounts of SX reagent reaching a local trout stream in tailings decant solution. Metallurgically, SX would have been the logical choice.

2) At the HOMESTAKE MINING COMPANY, Lead, South Dakota, in late 1984, an oil slick was observed floating on the surface of CIP adsorption tanks. Diesel-driven equipment is employed underground to mine the ore. Carbon adsorption process performance would be severely impacted by the presence of oil in the pulp as carbon selectively adsorbs gold and is thereby rendered hydrophobic. This occurrence at a leading U.S. gold mining/milling operation is not at all unique and must be guarded against wherever mechanical equipment is used in mines.

Even where an underground conveyor system is installed, overzealous greasers can introduce excess grease to an ore.

3) At PRESIDENT BRAND G.M. CO. LTD. in Welkom, South Africa, part of the initially poor performance when the calcine CIP circuit was started up was ascribed to organic species in the recycled water used at the plant.

4) Flotation of gold and pyrite from Witwatersrand ores is believed by operators to be adversely affected when treated sewage water is blended into the water supply. Extensive tests have been performed at the ANGLO AMERICAN RESEARCH LABORATORIES, but results show sporadic reproducibility.

5) Testwork at ANGLOVAAL RESEARCH LABORATORIES has indicated that if sewage is treated by the conventional biofilter process the effluent, when used for flotation, results in impaired recovery of gold and pyrite. However, if treated by the activated sludge process, the water can be used in flotation without these problems. However, the tests were preliminary and require confirmation on more samples. The quality of treated sewage effluents from the two plants has subsequently been shown to be highly variable. A trip report on the STILFONTEIN Sewage Treatment Works in Appendix I provides data on the variability of water quality from municipal water treatment works in small towns.

6) At the PRESIDENT BRAND GOLD MINING CO. it has been found that if recycled water containing a blend of treated sewage effluent is used in the flotation plant, recovery of gold and pyrite may drop sporadically. If, however, the water is first used as cooling water in the Peabody scrubber which is installed in the roaster-acid plant gas entrainment system, then this negative effect on flotation is avoided. In the Peabody scrubber, the water is exposed to heat and SO_2 gas.

7) Chris Flemming of the Council for Mineral Technology, MINTEK, in Johannesburg, undertook a test in which carbon adsorption efficiency for gold recovery was tested after addition of each of a long list of commonly used organic reagents such as flotation reagents, flocculants, etc. Although in most cases the effects were negative, there were some cases in which gold adsorption and recovery was actually enhanced.

8) At GIANT YELLOWKNIFE MINES, a gold mine at Yellowknife, Northwest Territories of Canada, carbon in leach is used to recover gold from precipitator dust collected from the roaster gas entrainment system. This dust contains arsenic and iron oxide as well as other constituents. GIANT YELLOWKNIFE adds 0.8 lbs. of an amine acetate flotation reagent which is found to improve leach recoveries. Falconbridge believes that the amine acetate helps release gold from arsenic compounds in the dust.

9) At NORANDA's Mattabi operations, recycled water accounts for about 70-75% of total mill water needs. Collector is used as sparingly as possible as otherwise it follows the recycle water back to the front of the process where it causes problems in that selectivity of the primary flotation step is interferred with.

10) Several gold mill tailings dumps have been used over the years as convenient unofficial dump sites for waste oils by industry. Now that this tailings material is being processed again, this oil can cause problems in the carbon adsorption of gold. Wherever tailings are to be reprocessed, operators must always be on the lookout for oils as in some cases the contaminated sand may be segregated to minimize the problem.

11) When TENNECO's Borealis heap leach operation started up in Nevada, the clarification filter and zinc precipitate filter press was soon clogged up by an oily substance. It was found to be related to an aqueous emulsion washed off the asphalt pad surface by the pregnant solution. The type of asphalt sealant used turned out to be critical. In this case, zinc precipitation was used, but carbon adsorption would experience equal problems if the carbon was exposed to the same organics. Larry Hartzog of BECHTEL, San Francisco, investigated the problem and may have further insights.

12) When surface ore in a desert environment is heap leached using alkaline cyanide, occasionally organics can be introduced to the ore and hence solutions by creosote bush roots that are crushed with the ore and saponified by the alkali solution.

13) In one of the base metal mines where backfill is used, concern was expressed that organics in the water resulted in poor cement strength of the backfilled stopes.

14) At AMAX's Mount Emmons project, Crested Butte, Colorado, control of the plant treating minewater was interfered with by a coating of saponified oil that coated the pH probes whenever underground exploration/development activity was in progress. This was found to be the result of hydraulic fluids from underground equipment reacting with lime used for pH adjustment to yield a suspension which coated on the probe.

15) Organic flotation reagent degradation products were detected in mill effluents at the New Lead Belt, Missouri, by JENNETT and WIXSON (1973), JENNETT and WIXSON (1977), JENNETT and CALLIER (1977), and discussed in general by JENNETT (1976).

According to JENNETT and CALLIER (1977), organics extracted from samples of effluent were taken from a control stream and two different mill treatment systems were generally $CHCl_3$ soluble and were extracted more efficiently when the

extractions were performed between pH 3 and 7. Data strongly implied that rainfall and runoff dilutes trace organics from the two mills. There was also no evidence of a correlation between pH, turbidity, alkalinity, COD, etc., and the level of trace organics extracted from a sample.

In spite of having identified organic species in mill effluents which are partly recycled, at least in the case of one of the mills, no evidence of a negative effect on mineral recovery has been identified at the New Lead Belt mines of AMAX or ST. JOE MINERALS.

16) Various types of dust control chemicals are used around open pit mines and haulways. One product that is believed to be very effective is a range of ligno-sulfonates which is a by-product of the pulp and paper industry. One industry observer has indicated that this type of product plays havoc with flotation performance if the roadway is ultimately mined and milled. The effect of ligno sulfonates on flotation is discussed in more detail in Chapter 54.

BARBARA A. KREBS
Technical Consultant - Metallurgy
ARCO Corp.
2397 515 South Flower Street
Los Angeles, CA 90071
(213) 486-3511

CONKLIN PRODUCTS offers a reasonably cost-effective liquid dust control product. This liquid contains a variety of glycols and alcohols and, as such, would likely interfere with carbon adsorption of gold from pulps or solutions if it were to get into the ore or process water at such operations, but this cannot be said with any certainty unless tested.

17) Several years ago when the mining camp serving the Climax Molybdenum Mine at Climax, Colorado, was located at Climax, mining camp sewage was discharged with tailings. Tailings solution was decanted for reuse in the mill. However, because of interference in flotation by organic species added with the sewage, activated carbon was added to remove them. Since the mining camp has been relocated to Leadville, sewage is no longer discharged with tailings, and carbon addition is no longer necessary. Climax Molybdenum staff demonstrated the effect on flotation recovery when sewage was discharged with tailings in the laboratory; however, quantitative data is not available as these tests were performed many years ago.

18) FISHER and RUDY (1976) carried out tests to determine which constituents of waste water, such as secondary treated sewage effluent, were detrimental to the flotation of molybdenite and copper sulfides. These tests included treating the waste water in Barnstead cartridges to remove specific groups of ions and assessment of the effect on the flotation metallurgy of the treated water.

Fig 1 Molybdenite recovery versus pH for demineralized water (D W.) and sewage effluent (S.E.). After Fisher and Rudy[1]

Fig. 2 Molybdenite recovery versus pH for demineralized water (D.W.), sewage effluent (S.E.) and activated carbon (A.C.). After Fisher and Rudy[1]

Some of the experimental results obtained from the flotation tests are illustrated in their Figures 1 and 2. These results were summarized as follows:

a) The use of sewage effluent caused a decrease in recovery of 16.2% for MoS_2 and 2.4% for copper sulfides.

b) Dilution of the sewage effluent with distilled water resulted in a proportionate decrease in the detrimental effects associated with the use of waste water effluent.

c) Removal of cations from the sewage effluent resulted in a slight improvement of the recoveries.

d) Removal of the anions from the sewage effluent resulted in the most significant improvement in copper and molybdenum recovery.

e) Foam fractionation to remove surface-active material did not improve the quality of sewage effluent and, hence, the recoveries were at the same level as with untreated sewage effluent.

f) Tertiary treatment of sewage effluent by activated carbon resulted in a significant improvement in water quality in terms of recovery of metals but not to the level achieved by removal of anionic species.

Similar results have been reported by many concentrators that have attempted to recycle process water, but published data on the effects of recycle water are scarce. All known data demonstrate a strong influence of soluble water constituents on the recovery of molybdenite and provided the basis for a more detailed review by HOOVER (Post 1979), which is inserted in Chapter 54 on water quality effects in flotation processes.

Apart from the important effects mentioned above, it is known that hydrophilic polymers and ligninsulfonates are excellent depressants for molybdenite, e.g., dextrin, starch, glue, dyes, and condensation products of aldehydic substances with aromatic sulfonic acids. In addition, tannic and humic acids known to exist in recycle mill waters are known to depress molybdenite.

One of the strongest depressants of molybdenite are ferric ions which are commonly found in recycle mill solutions, especially in the presence of calcium. Colloidal slimes also have very great impact on molybdenite supression.

19) HISCOX and BUZA (1975) described a new system using lignin sulfonate to depress molybdenum sulfide. The ANACONDA CO.'s Metallurgical Research Dept. discovered

that large quantities of lignin sulfonate in combination with a high pH milk-of-lime depressed the molybdenite while allowing talcs and clays to float.

Elsewhere, where small quantities of lignins got into process water due to decay of underground timbers, the froth in flotation plants is reported to have become uncontrollable, and the concentrate at at least one copper moly mill is said to have spilled to the floor sump when lignin from natural sources got into the water.

20) Many gold leaching plants employ air agitation in pachucas. Similarly, air agitation may be used for carbon-in-pulp adsorption vessel agitation. Many air compressors employ oil lubricated pistons and unless the compressed air is cleaned of oil through use of an oil trap and filter, it will introduce oils to the pulp in the leach and CIP stages. This oil will blind the activated carbon and interfere with gold adsorption and recoveries.

21) At FALCONBRIDGE's Onaping Mine, Onaping, Ontario, small volumes of raw sewage are discharged to a settling pond together with underground minewater to which NaOH is added to precipitate nickel. The sewage settles to the bottom of the pond together with $Ni(OH)_2$ which is precipitated and accumulates as a bottom layer. As the sewage undergoes bacterial degeneration, gases (methane) are generated which attach to particles of bottom sediment. As a result, pieces of sediment rich in nickel float to the surface and leave the settling pond with decant solution, ultimately to find their way to the main tailings decant system and the effluent discharge to the receiving waters where a maximum limit for Ni has been set at 1 ppm. Not much of the floated sediment running 5-10% Ni need get into a water sample to wreak havoc with monitored results.

PREVENTION OF ORGANICS CONTAMINATION OF PROCESS WATER/EFFLUENTS

Very often the contamination of metallurgical process water and effluents can be prevented by eliminating the source of the contamination. This may require making the mining or maintenance department aware of the impact of malpractices on overall metallurgical efficiency and profitability.

1. At INCO LTD.'s Copper Cliff operations, a survey of supplies consumed underground led to the observation that the consumption of hydraulic fluids was excessive. Further investigation led to the discovery that hydraulic lines on underground equipment were rupturing far too frequently despite the fact that operating pressures were within limits. It was established that the pressure ratings of the lines at elevated underground temperatures had to be reduced. Replacement of hydraulic lines by a more expensive version solved the problem, reduced

consumption of hydraulic lines and fluid, and resulted in an improvement in metallurgical performance.

2. Very often, mine tailings and decanted tailings water are impounded in densely wooded terrain. One recommendation is to avoid contact between water that is to be recycled to the mill or discharged as an effluent with rotting vegetation and timbers. Rotting vegetation can introduce humic acids into water which chelate metals and may interfere with metal or mineral recovery processes.

3. It is essential that underground mine supervisors and maintenance/lubrication crews be made aware of the costly consequences of lubrication oil, fuel, hydraulic and cleaning fluids, greases, etc. being discarded or applied excessively in the mine. Through good housekeeping, education, and discipline, excess organics can be kept out of the ore and minewater in the first place. In observing lubrication crews going underground carrying grease canisters, it is interesting to note how many bring a used or half-used canister back out of the mine. The question remains as to the fate of the unused grease and the empty canisters that remain in the mine.

4. Mine tailings areas should always be fenced off and/or patrolled. Today's tailings can well become tomorrow's ore and should be inaccessible to the dumping of toxic or oily wastes by local service stations, etc.

5. Mine management can do a lot to avoid organic contamination of ore and water through surveying the quantities and fate of all supplies consumed in the mine as well as the disposal practices of waste from workshops and maintenance areas.

6. If surfactants are used for dust control, the possible effect of these on metallurgical processes should be examined in the laboratoy and in the field through appropriate testing. This could allow potential problems to be avoided through appropriate product screening.

7. On the Witwatersrand, a new type of hydraulic power is under development in which the hydraulic head of water from the surface to the underground workings is used to hydraulically power mine drills and other tools as well as to generate hydropower underground. Replacement of organic hydraulic fluid with water will in fact avoid a considerable potential for contamination of ore and mine water with hydrocarbons from leaking hydraulic equipment and lines. However, the water used will be mixed with an additive, and it remains to be seen what the effect of this additive is on metallurgical processes.

8. At all Witwatersrand gold and uranium recovery operations, the use of treated municipal sewage effluents in the mines as cooling water is under consideration. Due to the severe recent drought, uses for this water within the mine/mill complex are also being investigated. In gold and uranium circuits, there have been no adverse effects on some mine-mill complexes (see Vaal Reefs). However, for flotation circuits, more needs to be known about how the sewage was treated and careful laboratory tests of several samples undertaken to be sure that it is suitable on a site-by-site basis.

TREATMENT FOR REMOVAL OF ORGANICS

Although prevention is better than cure, organics can be removed from water in the following ways:

1) Physical Skimmers
2) Adsorption Devices
3) Activated Carbon Treatment
4) Dissolved Air Flotation
5) Biological Processes

PHYSICAL SKIMMERS

Physical skimming devices generally are applicable for the recovery of petrochemicals from small water impoundments containing relatively high concentrations of imiscible organics which float on the surface.

Skimmers of different sizes and capacities are offered by:

1) SLICKBAR, INC.
250 Pequot Avenue
Southport, CT 06490
(203) 255-2601
Telex: 043458

2) MEGATOR CORP.
562 Alpha Drive
Pittsburgh, PA 15238
(412) 963-9200
(800) 245-6211

3) OIL RECOVERY SYSTEMS, INC.
1420 Providence Highway
Suite 128
Norwood, MA 02062

4) PRICE-DANNELL, INC. OF AL
1135-F Hutson Drive
Mobile, AL 36609

5) HUDSON INDUSTRIES
Department P
Box 2212
Hudson, OH 44236

6) FRAMCO
9 Tipping Drive
Branford, CT 06405

ADSORPTION DEVICES

For example, small amounts of oil can be removed from the surface of a water impoundment by installing a floating adsorbant boom across the overflow weir of a settling pond.

At AMAX's Mount Emmons water treatment plant, an adsorbant boom is installed on the settling pond. It was supplied by:

1) ENTROL ENVIRONMENTAL SERVICES, INC.
1390 East Burnett Street
Signal Hill, CA 90806
(213) 424-6016

2) ENTROL ENVIRONMENTAL SERVICES, INC.
1303 Canal Avenue
Richmond, CA 94804
(415) 234-3887

This adsorbant boom is effective in removing a small quantity of floating hydraulic oil from minewater which otherwise ultimately saponifies at pH adjustment by lime and coats the pH probe resulting in malfunction of the automatic pH adjustment system.

ORGANICS CONTAINMENT BOOMS

Floating organics spills can be contained using floating booms. Suppliers include:

1) SLICKBAR, INC.
250 Pequot Avenue
Southport, CT 06490
(203) 255-2601
Telex: 643458

2) GLOBE INTERNATIONAL, INC.
Box 1062
Buffalo, NY 14240
(They also supply flameproof spill barriers.)

OIL RECOVERY SYSTEMS

By recovering usable oil from waste crankcase oil, for example, less waste oil requiring disposal is generated. The use of such systems may result in less chance for waste oil dumping on site with possible future metallurgical interferences. Oil skimmers are used in many underground mines including ST. JOE MINERALS' Fletcher Mine at Boss, Missouri.

Various oil reclamation equipment suppliers include:

1) AQUANETICS, INC.
111 Milbar Blvd.
Farmingdale, NY 11735

2) MEGATOR CORP.
562 Alpha Drive
Pittsburgh, PA 15238

ORGANIC SOLVENT REMOVAL AND RECOVERY

Air stripping removal of volatile organics from water:

1) NEPCCO EQUIPMENT DIVISION
29 Wall Street
Foxboro, MA 02035

Activated charcoal adsorption:

1) DEDERT CORPORATION
20000 Governor's Drive
Olympia Fields, IL 60461
(312) 747-7000
Telex: 25-3889

CARBON ADSORPTION SYSTEMS

1) DEDERT CORPORATION
20000 Governor's Drive
Olympia Fields, IL 60461
(312) 747-7000

2) CALGON MOBILE TREATMENT SERVICE
Calgon Corporation
Activated Carbon Division
Post Office Box 1346
Pittsburgh, PA 15230
(412) 777-8000
William D. Faulkner

BIOLOGICAL PROCESSES

Biodegradable organic constituents are routinely removed from wastewater in more sophisticated sewage treatment plants, and books have been written on the subject. Two commonly used approaches are biofilters, usually trickle filters, and activated sludge plants. Both of these seem to depend on relatively high nutrient concentrations in feedwater. An important report on this subject has been prepared by VIVIERS (1980), and water impoundments allow bacterial action to remove some of the undesirable organics in reclaimed tailings decant water prior to recycle to the plant although not one case was found where this had been quantitatively evaluated. Some industry observers have simply observed that the aging of recycled water in a tailings dam results in improved metallurgy. VIVIERS (1980) refers to a R500,000 aging pond installed for this purpose at the Black Mountain Cu-Pb-Zn recovery operation in South Africa.

A most interesting application of an engineered marsh for sewage treatment at a small installation such as a mine-mill complex was demonstrated in Canada where a cattail bog was engineered and tested as a demonstration unit. More information on this innovative biological system is described by BLACK (?) and WILE, PALMATEER, and MILLER (?), or from:

ONTARIO MINISTRY OF THE ENVIRONMENT
135 St. Clair Avenue West
Toronto, Ontario M4V 1P5
S. A. Black
I. Wile

The use of meander systems with plants and algae have been indicated to remove organic species from water with efficiency as described in the New Lead Belt Study by WIXSON (1977).

TREATMENT FOR REMOVAL OF ORGANICS

1. A Cu-Pb-Zn mill in Ontario recovers copper, lead, and zinc concentrates from a mixed sulfide ore. Activated carbon is or was in the past added to the Cu-Pb concentrate to remove any extraneous collectors before the Cu-Pb separation. Concentrate feed is heated to 120°F to disperse Minflo 5007 and conditioned for 30 minutes before further conditioning with SO_2. Then, a collector 2030 (a dithiocarbamate) is added to float the copper from lead. The addition of activated carbon helps achieve a better Pb-Cu separation. Precise details have not been confirmed by the parent company.

2. This mill operates/operated its primary bulk float at starvation collector levels. Too much collector at the front end ruins selectivity of Cu-Pb versus zinc. Some Cu-Pb recovery is sacrificed to keep zinc out of the copper concentrate. Presumably, the addition of carbon helps remove any excess collector that might otherwise return to the front of the process with recycle water although presumably excess collector would be lost with the zinc concentrate solids, and very little would follow the solution.

3. AMAX at their Climax Molybdenum Mine in Colorado formerly discharged raw sewage from their Climax mining camp with tailings. To avoid metallurgical interference at the float plant, activated charcoal was added to tailings to remove organic species from the decanted tailings water which is recycled to the mill. After the mining camp was moved to Leadville, however, sewage discharge to tailings stopped, and it was no longer necessary to add carbon. The carbon addition was last practised many years ago, and the old data on the effect on mill recoveries is no longer available.

4. Many mine-mill complexes employ very large mill tailings dams and water impoundments. Aging of water that is to be recycled and contact with mill tailings solids appears to render the water more suitable for use in mineral processing and metallurgical operations. This is certainly also the opinion of BOLIDEN METALL AB.

5. Where treated sewage water is to be used in a mill, particularly one using flotation processes, possibly installation of a well-run activated sludge process in the sewage plant would render the water quality suitable for use in the mill without losing metallurgical efficiency. Recently, AFROX LIMITED in South Africa introduced their VITOX process which enhances biological oxidation of organics in sewage plants by injecting oxygen into the system ahead of biofilters. One such system was installed in the STILFONTEIN GOLD MINING COMPANY hostel sewage treatment plant. More information is available from:

AFROX LIMITED
Post Office Box 4100
Germiston South 1411
(011) 825-1355
Telex: 4-27090
Jeanette Lewis

To date, no information has been developed on the effect of VITOX on water quality at Stilfontein as far as its possible impact on flotation recovery of gold and pyrite, as far as the use of reclaimed sewage effluent in the mill is concerned.

Since VITOX would be rendered unpractical at many mine-mill complexes due to the distance from an oxygen supply, new oxygen generation technology may prove of interest. ALBANY INTERNATIONAL CORP. has recently developed a reverse-osmosis type membrane for oxygen enrichment from air at a relatively low pressure (100-200 psi). More information is available from:

ALBANY INTERNATIONAL CORP.
Membrane Development Venture
921 Providence Highway
Norwood, MA 02062
(617) 796-6310
Alla Kan
Myron J. Coplan
General Manager

6. At the AMAX-Homestake lead zinc mill at Buick, Missouri, effluents are discharged to the river system after flowing through an artificial meander system. WIXSON (1977), in a report on the environmental impact of mining and milling on the New Lead Belt, showed data developed by W. C. Jennett and coworkers that organics in the effluent are effectively removed by algae in the meander system. A lead to additional sources of information can be obtained from:

DR. BOBBY G. WIXSON
Director of Environmental Health
Center for International Programs
and Studies
University of Missouri - Rolla
Rolla, MO 65401
(314) 341-4208/341-4483

7. Underground hydraulic fluid leaks are not identified as a cause of metallurgical efficiency loss in the mills on the Witwatersrand although undoubtably any hydraulic fluids finding their way into ore underground would have an impact on pyrite-gold flotation and on CIP adsorption efficiency.

Nevertheless, motivated by economic incentives, the Chamber of Mines of South Africa has successfully developed hydraulically powered underground equipment which use water instead of organic liquids such as hydraulic fluid. Chilled water is pumped underground to cool the work environment, and the hydrostatic head of this

water is adequate to drive rockdrills and other equipment. Replacement of organic hydraulic fluids with water-driven tools may also reduce the opportunities for contamination underground due to line breaks, leaks, and from maintenance areas. As mentioned above, this hydraulic water is mixed with an additive.

8. At the Simmer and Jack secton of SIMMERGO LTD., a CIP plant was installed in 1982 to recover gold from reclaimed tailings on the Witwatersrand just east of Johannesburg. The tailings pulp was brought into contact with carbon on two dummy CIP contactors before cyanidation with the intention of removing organics from the pulp that otherwise would interfere with gold adsorption in the CIP section after cyanidation. It is not yet known how effective this step was. More information could be requested from:

EAST RAND GOLD AND URANIUM
COMPANY LTD.
Post Office Box 890
Brakpan 1540
(011) 559050
Harry Brown,
Project Manager

9. GENCOR, at the Chemwes tailings treatment plant at Stilfontein, Transvaal, has reputedly tested organics removal by carbon adsorption ahead of cyanidation and CIP. It is understood that the pilot plant operated in 1983-1984 to test this process performed very well. The GENCOR contacts with knowledge of these tests are:

GENCOR LTD.
Box 1820
Marshalltown 2107
(011) 836-1121
P. Van Aswegen

CHEMWES LTD.
Post Office Stilfontein,
Transvaal
(011) 41131
Piet Haasbroek

10. GENCOR at Buffelsfontein Gold Mining Co. Ltd. adds powdered activated carbon to repulped gold plant filter tailings to recovery incremental gold. The gold on carbons is recovered in the subsequent flotation step. If there were any organic contaminants in the pulp, these would also conveniently be removed ahead of the flotation plant. This process will be described by VAN ASWEGEN (1985).

11. When carbon adsorption is employed for gold-silver recovery, it is essential to keep oils and greases from the feed pulp and solutions to avoid fouling carbon as mentioned above. If compressed air is used for pre-aeration of the pulp to oxidize phmhotite, or for cyanidation leach agitation or for CIP adsorption agitation, or even for carbon transfer within the plant, then it is important that the air used for the

purpose be passed through an oil trap and filter to remove compressor oil that is usually entrained.

12. Dissolved air flotation is effective in removing organic emulsions from aqueous streams. For example, DAF can be used effectively to recover entrained solvent extraction organics from raffinates. More information on this application which has been demonstrated at copper recovery plants would be available from:

POLLUTION CONTROL ENGINEERING, INC.
10751 South Lakewood Blvd.
Downey, CA 90241
(213) 861-1297

13. Humic acids derived from decaying organic matter of plant origin and fumic acids derived from decaying animal matter may, if present in process or effluent waters, result in the chelation of metals rendering them less easily removed from effluents by conventional lime-settle-filter processes. They may also interfere in some metallurgical recovery processes although no hard evidence was encountered during this investigation.

The Rohm & Haas Company has developed an experimental polymeric coagulant XE-392 which is said to be effective for humic acid removal in addition to its primary design function of removing trihalomethanes from potable water. In 1983 this product was not yet on the market, but further inquiry could be direct to:

ROHM & HAAS COMPANY
Independence Mall West
Philadelphia, PA 19105
(215) 592-2817
Fred Flor

14. Solvent extraction organics are often lost in crud which is generated in SX plants in both copper and uranium recovery operations. Often this CRUD is dumped, and it can introduce organic contaminants to surface and groundwater.

A company in South Africa has developed a process employing pressure filtration followed by phase separation in a settler to recover solvent extraction reagents from CRUD:

EFFLUENT CONTROL (PTY) LTD.
Post Office Box 586
Isando 1600
South Africa
(011) 974-1131
Telex: 8-9062 SA

15. VIVIERS (1980) describes laboratory experiments to determine whether biologically activated sludge can be used for the removal of organic contaminants from flotation plant recycle waters. A synthetic sewage spiked with isopropyl thionocarbamate (Z-200) and sodium ethyl xanthate (SEX) was passed through a small test plant that had a capacity of 2.5 litres. When the concentration of SEX in the sewage was 20 ppm, the test plant removed it completely. No more than 23 percent of the Z-200 could be removed under the typical conditions described.

VIVERS (1980) also provides an interesting literature review of the effects of reagents in recycled process water described for other cases and measures adopted for their removal. Workers interested in this aspect could get in touch with him at:

16. Water quality problems necessitated a change in metallurgical process for the separation of copper-molybdenum at San Manuel, New Mexico. The San Manuel-developed process, which employed $FeCl_3$ or H_2O_2 for the Cu-Mo separation from a bulk sulfide concentrate, had to be abandoned in favor of the addition of NaHS which is now the more commonly employed process for Cu-Mo separation by flotation in the southwestern U.S.A.

The reason for this change and the reason their process did not work as well as expected in the field was that when recycled mine and mill tailings water was used, oil contamination severely impacted the $FeCl_3$ and H_2O_2 addition process efficiency but had a much less pronounced effect on the NaHS depressant process.

More information may be available from Richard Johnson who is now at:

17. FISHER and RUDY (1978) reported results of an investigation of municipal waste water constituents detrimental to froth flotation recovery of copper and molybdenum sulfides. They found that the substitution of secondary treated sewage effluent for normal water in laboratory tests simulating froth flotation recovery of copper and molybdenum sulfides caused a significant deterioration. First, a voluminous froth that is difficult to control and has little mineral carrying ability was generated, even in the absence of a frothing agent. Second, sewage effluent caused a small but significant loss in copper recovery and a large loss in molybdenum recovery.

Removal of surfactants from sewage effluent by foam fractionation eliminated the unmanagable froth but had no effect on the loss in metal recovery. The component of sewage effluent responsible for the loss in metal recovery was found to be an anionic organic substance that has an effect similar to humic acid. One method of water conservation can be realized by the use of municipal waste water for purposes that do not require high quality water. In areas where sizable mining activity is present adjacent to a city, it may be possible to substitute municipal waste water for the surface and ground water normally used in the processing circuits. This investigation was prompted by such a possibility in Tucson, Arizona. These authors were unaware of the successful use of activated carbon to overcome observed problems as practiced years ago at the Climax Molybdenum Mine.

17. South African uranium plant operators avoid the use of cationic flocculants for solid/liquid separation ahead of SX recovery plants. The reason for this is not clear to SOUTH AFRICAN CYANIMID staff. Gold plants in South Africa use cationic flocculants for clarification. Cationic flocculants are also used in uranium plants by NUCLEBAS BRAZIL and some Canadian and French operations. Nevertheless, tradition has it in South Africa that cationic organic flocculants interfere with solvent extraction recovery of uranium. More information may be available from:

19. SUPERCHARGED OXYGENATED ACTIVATED SLUDGE PROCESS

MEGOX Process - A small activated sludge sewage plant operated on pure O_2 employing a single tank to process the sludge. The process destroys NH_3 and 70-90% of incoming organics depending on residence time. The idea is to install small rougher sewage plants at the site of effluent generators which otherwise could overload municipal plants.

Municipal plants charge their industry clients a fee based on load and flowrate of sewage discharge. By knocking out the worst of the load, the cost of municipal service will be reduced.

MEGOX is ideal for phenol removal as municipal plants do not want phenols.

The MEGOX process is offered by:

AFROX LTD.
Post Office Box 4100
Germiston South 1411
(011) 825-1355
Jeanette Lewis
Preston White

The vendors claim that the MEGOX process destroys cyanide generated in coal coking process effluents.

WIMPY UNOX PROCESS - In the U.S.A. a similar process known as the Wimpy unox process is offered by the UNION CARBIDE CORPORATION. It is apparently very similar to the MEGOX process except that it employs an enclosed acitvated sludge reactor with a pure oxygen atmosphere above the sludge. Oxygen levels in water saturated with air can reach 8 mg/l O_2 but with an oxygen atmosphere, the dissolved oxygen levels are boosted to 40 mg O_2/l. Oxygen dissolution in water obeys Henry's Law:

$$[O_2] \text{ dissolved} \propto p[O_2] \text{ atmosphere over water.}$$

AFROX VITOX PROCESS - AFROX has also developed a patented design to draw sludge from the bottom of the reactor and to oxygenate it using a Bell oxygenator. They have also patented a Venturi Vitox O_2 injector. Oxygen is sucked into the venturi for flash mixing with sludge pumped through the venturi. The oxygenated sludge is then sparged back into the tank via a special nozzle.

The VITOX nozzle air dissolution technique can be employed also for CO_2 dissolution. CO_2 used for pH adjustment does not raise the TDS.

VITOX is installed at several effluent dams for odor control of anaerobic effluents.

MEASUREMENT OF ORGANICS IN WATER

The measurement of organics in process solutions and effluent is relatively difficult largely because there are so many different kinds of organic compounds. This task is partly described in STANDARD METHODS (1960).

This aspect was not examined in any depth. It was established that the Bureau of Mines in Salt Lake City, Utah, had been involved in a project to develop methods to measure

Sorbent Rolls
E 150

Ergon Sorbent Rolls are designed for use in sumps, along shorelines and ground areas, and for open-water control and recovery of rainbow sheens and thin slicks. They may be used to protect floors and walkways where chemical or oil leakage is apt to occur. Sorbent rolls ar quickly deployed and measure 36"x150'x⅜".

Recyclability

Ergon Oil Sorbent can be reused 30 to 50 times, depending upon the method of oil removal used. Oil can be removed by wringer, centrifuge, or solvents. Over 90% of absorbed oil may be removed without damaging the sorbent material. This capability reduces the amount of sorbent material needed to effectively respond to spills.

Availability

With storage warehouses throughout the Southern United States and dealers in strategic locations throughout the country, you have 24 hour access to Ergon Oil Sorbents.

For availability nearest your operations write or call:

INTRODUCTION

Phosphate contamination of surface waters has become of major concern in most population centers. Phosphates, along with nitrogenous compounds, are key nutrient building blocks not only for plants, but also for algae and bacteria. Excessive phosphate levels in water promote algae and bacterial growth to the extent that it can be so prolific that resulting biomass degradation demand for oxygen can exceed the rate at which oxygen can be replenished. The result is asphyxiation of aquatic life, aesthetic damage, and ugly odors. On the other hand, addition of lesser amounts of phosphate to water actually enhances aquatic life.

OCCURRENCE OF PHOSPHATES IN WATER

Phosphates enter the environment via treated and untreated sewage effluents. Phosphates enter sewage largely as a result of the use of phosphate-containing household detergents although the use of this type of detergent is increasingly being discouraged. Phosphates also enter surface waters in runoff from agricultural land fertilized with phosphate-containing plant foods. Lawn fertilizers containing phosphate applied in a built up area can enter the sewage system via runoff and stormwater drains. In some parts of the

world such as the Pretoria-Witwatersrand-Vereeniging-Sasolburg area of South Africa where sewage treatment plant effluents are discharged back to the drainage of the Vaal Dam and Vaal Dam water is effectively reused many times, the TDS, phosphate, and chloride levels are likely to increase. There is real concern in the Witwatersrand region about the need to reduce phosphate levels in effluents which drain into the Vaal Dam and other recreational bodies of water in the area such as the Hartebeespoort Dam. The Witwatersrand is but one of several such areas in the world.

As a result of this serious general concern for the need to limit phosphate levels in effluents, strict limits on phosphate have been legislated in many major metropolitan areas around the world.

Although mining districts (except the Witwatersrand) are in general relatively remote from heavily populated metropolitan areas, the rules governing phosphate levels in effluents may be generally applicable there as well.

PHOSPHATES IN MINE-MILL ENVIRONMENTS

In phosphate mining areas, one would expect relatively high levels of phosphate in surface and groundwaters. ROUSE and BROMWELL (1983) studied the phosphate levels in groundwater resources of the central Florida area and concluded that:

1) The mining and milling of phosphate rock and the subsequent acidification for production of phosphoric acid has the potential for severe impacts on groundwater resources of the central Florida area.

2) The area is, however, characterized by extremely high geochemical removal capacity which has resulted in the minimizaton of contamination. Contaminant plumes, characterized by reduced pH, elevated metal concentrations, saturated calcium sulfate solutions, and active geochemical mechanisms are only a few feet in lateral and vertical extent. The geochemical removal mechanisms are extremely efficient in removing radionuclides with the result that no significant radionuclide concentration is expected to advance more than a few meters from the source. Sulfate forms the best tracer to evaluate for contaminant mobility from phosphorus processing operatons.

In non-phosphate mineral processing facilities, phosphate can enter the process water system through the addition of anti-scaling reagents which often consist of phosphonates which degrade to orthophosphate if dosed in excess of real needs to inhibit scale.

However, in the mine-mill environment, phosphates generally also enter the system primarily in sewage or sewage treatment plant effluents. This would be particularly noticable in those parts of the world where mining and mineral processing is more labor intensive, for example in Africa and South America. Witwatersrand mineworker hostels house several thousand miners each, and mine clothing is laundered using detergents. Detergents are used to scrub down the facilities and kitchens and may sometimes be used in indiscriminate quantities which introduce phosphate to the overall sewage system which ultimately may find its way to mine tailings or be discharged to the local drainage from where it ultimately finds its way to the Vaal River and/or Vaal Dam.

Professor M. J. Hamlin, Professor of Water Engineering at Birmingham University, who has extensive experience in water-related problems on the Witwatersrand, was quoted by STEWART, SVIRIDOV, and OLIVER (1981) as follows on the practicability of including nitrates and phosphates as pollution parameters in a mathematical model for salt and water balances for the region:

"The modelling of phosphates and nitrates is extremely complex and I have not been able to give more than superficial consideration to this problem. It is not clear what additional physical information may be necessary to construct adequate models, but if the Welkom Dam is to be built, I consider it to be essential to know how nutrients might build up in that reservoir and in the Bloemhof Dam. This suggests that in the current monitoring scheme administered by the Rand Water Board, it would be appropriate to include in the daily analyses at the major points of interest, nitrates, phosphates, and chlorides in addition to TDS."

INFLUENCE OF PHOSPHATE ON METALLURGICAL PROCESSES

In the course of this investigation, no direct correlation was found between PO_4^{3-} in water and metallurgical recovery efficiencies, possibly because no one has looked for such a correlation.

In South Africa, at any rate, it is generally believed by operators that when treated sewage water is blended back into the process water, metallurgical inefficiencies are bound to result. Mill operator understanding of the species in sewage water which cause the problems in flotation recoveries is non-existant. Also, mill operators have little or no understanding of sewage treatment processes and do not distinguish between raw sewage, treated effluent by biofiltration, oxygen enhanced (VITOX) biofiltration, and the activated

NO_3^- & PO_4^{3-} IN TREATED SEWAGE WATER

sludge processes (including Phoredox), nor between various levels of sophistication of operation of these processes--to them all sewage is detrimental.

Since phosphate is added to process water through degradation of commonly used scale inhibitors, apparently without introducing metallurgical problems, it is likely that phosphates themselves in treated sewage waters are not the species responsible for metallurgical interferences. The presence or absence of phosphate may be indicative, however, of the extent to which the unidentified deleterious species have been removed in the sewage treatment process.

There have been preliminary indications that sewage water treated by the activated sludge processes may not have detrimental effects on the flotation of pyrite and gold at high pH as opposed to product water from an adjacent biofiltration plant at Stilfontein, Transvaal. These preliminary but interesting laboratory tests were carried out, and more details could be requested from:

ANGLO-TRANSVAAL RESEARCH
LABORATORIES
Post Office Box 1
Florida 1710

Dr. Gerhard Overbeek

LOVELL, et al. (1971) investigated the flotation of phoscorite ores to examine possible correlations between chemical variables in solution and metallurgical performance with a view to improving performance of phoscorite recovery at Phosphate Development Corp. Ltd. (Foskor) at Phalaborwa. Strangely enough, they examined the levels of several contaminants in solution but did not monitor dissolved phosphate levels.

An interesting observation has been made that if phosphorus-containing scale inhibitors are used in excessive doses, the excess converts to ortho-phosphate and scaling effects can actually be enhanced.

ENVIRONMENTAL SENSITIVITY TO PHOSPHORUS

According to ONTARIO (1979), scientific evidence is insufficient to develop a firm objective for phosphate levels in water below which the aquatic environment will be protected. To avoid nuisance concentrations of algae in lakes, total phosphorus concentrations for the ice-free period should not exceed 20 ppb (ug/l). A high level of protection against aesthetic deterioration would be provided by total phosphorus levels for the ice-free period of 10 ug/l or less. In rivers, excessive plant growth would be eliminated at a total phosphorus level below 30 ppb.

PHOSPHATE

Natural algal and macrophyte growths in any lake or river are mainly influenced by the morphology of the water body and the supply of nutrients. The amounts and species of aquatic plants play a major role in establishing the physical appearance and total biological community of a waterway. Lakes with little algal growth will generally have clear water, low primary productivity, and low fish productivity. However, lakes with greater algal growth will be more turbid and have higher primary productivity and higher fish productivity.

It has been shown (ONTARIO, 1979) that phosphorus limits the algal and plant growth in many lakes and rivers and thus, to a large extent, controls the species present, the productivity, and the appearance of surface waters.

According to ZITKO, et al. (1970), phosphorus in the elemental state is very toxic to aquatic life, but this form does not occur naturally. Its occurrence in industrial discharge is a very rare occurrence.

Phosphorus in combined form is not toxic to aquatic life and does not need to be controlled to protect aquatic life from direct effects. Phosphorus levels must be controlled, however, to prevent undesirable changes in the aquatic ecosystem due to increased algal growth which will inevitably result from phosphorus addition to surface wastes.

Increased algal growth resulting from phosphorus inputs to surface waters can be a benefit in some cases by providing more food for fish. On the negative side, increased algal growth increases turbidity, thus reducing the aesthetic appearance of the water. The increased production of water requires more oxygen during decomposition and may adversely affect aguatic life in the bottom layers of lakes by reducing oxygen to unacceptable levels. Fish habitat and spawning grounds may be destroyed and, while total fish production may stay the same or even increase, there can be changes to less desirable species.

Macrophytes are the main form of plant growth of concern in rivers. Algal growth is not generally a problem, and ONTARIO (1979) considers 30 ppb total P to be a reasonable objective.

Regardless of all these wishes and desires, the fact remains that most sewage effluents (treated and untreated) are in the 1-10 ppm range rather than the ppb range that regulators would prefer.

In the trip report on the Stilfontein Sewage Works in Appendix I, the phosphate levels in raw sewage ranged from 5-10 ppm and in activated sludge treated effluents, from 3-6 ppm. The consulting engineer did not have data for the biofilter treated effluent. It is

interesting that the data in Appendix I shows that nitrogen and nitrate levels were reduced further by biofiltration than by this particular activated sludge plant.

REGULATORY LIMITS FOR PHOSPHORUS

Mine operating permits seldom include phosphorus or phosphates. Regulatory limits are, however, frequently imposed on effluents from sewage treatment plants in major metropolitan areas. In South Africa, for example, a new standard has been proposed in 1983 for the Witwatersrand area which would limit total phosphorus to 3.0 ppm P in effluents. Phosphorus in orthophosphate will be limited to 1.0 ppm P.

During the course of this investigation which included only one phosphate mine, no limits were found for phosphate in the mine effluent limits examined.

According to P. J. Pybus of Stewart, Svirirdov, and Oliver, a leading consulting engineer in the field of sewage treatment in Johannesburg, the 1 ppm PO_4^{3-} as P limit in the Witwatersrand is less stringent than in the U.S.A. where at Reno-Sparks, the limit on total phosphorus has now been reduced from 0.7 ppm P to 0.5 ppm P.

P. J. Pybus
Consulting Engineer

The South African Government Gazette, Volume 223, 13 January 1983, presented new regulations limiting phosphate contribution to surface waters by overfertilization of maize fields from which runoff drains into the Vaal River.

REMOVAL OF PHOSPHORUS

WILMOTH, et al. (1978, 1979) tested various technologies for the removal of trace elements from acid mine drainage. Lime neutralization, reverse osmosis, and ion exchange removed As, Cd, Cu, Hg, Ni, Cu, and Zn from acid mine drainage but did not remove B or P. The two-bed ion exchange system was ineffective for removal of P and B, and none of the methods tested removed P.

In practice, there are two main ways to remove phosphates from water--biological and coagulation. Biological processes generally refer to activated sludge processes and the more sophisticated variations thereof such as Badenpho and Phoredox developed by the National Institute for Water Research (NIWR) of the CSIR, Pretoria, South Africa. Biological phosphate removal could also include uptake by plants such as water hyacinths,

cattails, etc. Coagulation processes for phosphate removal generally involve the addition of other metal ions.

By far the greatest experience in phosphate removal belongs to municipal water supply and municipal wastewater treatment industries. With this in mind, an authoritative text on wastewater treatment by CULP, et al. (1978) is probably as useful a source of information as any.

CHEMICAL COAGULATION

Chemical coagulation of phosphate has proven consistently reliable and efficient on a plant scale according to CULP, et al. (1978). In an integrated biological-chemical process approach, the coagulant may be added either ahead of the primary clarifier or directly to the aeration tank in an activated sludge tank. When added ahead of the primary clarifier, alum, iron, or lime may be used. When added directly to the aeraton tank, iron or alum salts are used. If the physical chemical coagulation step is separated from the biological treatment, any of the above coagulants may be added to the secondary effluent with subsequent settling downstream. CULP, et al. (1978) compared the alternative approaches as follows.

PERFORMANCE - COAGULATION

Systems in which coagulation is integrated with the biological process achieve an overall phosphorus removal of 75-85 percent to levels of 1-2 ppm P. Subsequent filtration of effluents from such an integrated process may reduce phosphorus levels to 0.5 ppm P if the coagulant dose is proper.

If chemical coagulation of secondary effluent is applied as a separate process, lower phosphorus concentrations may be achieved. At the South Tahoe project, an average phosphorus concentration of 0.05 ppm P was achieved for an entire year.

By separating the chemical from the biological treatment steps, it is possible to employ efficient rapid mixing and flocculation devices and to optimize the coagulant dose solely for phosphorus removal without being concerned for the effects of such doses on the biological treatment system. The same features which achieve phosphate level reduction also achieve lower suspended solids in the final effluent when the physical-chemical processes are downstream of the biological process.

FLEXIBILITY

Separation of the chemical coagulation process from the biological process keeps the chemical and biological sludges separate. This provides the designer with more options in terms of coagulant choice and sludge handling. For example, the use of lime as a coagulant in a tertiary step has an advantage in that coagulant recovery may be achieved which reduces the quantity of sludge that must ultimately be disposed of and may provide a more economical coagulation process than the use of alum or purchased iron salts.

Separation of the chemical step also provides more operational flexibility to insure maximum removal of phosphorus where this is necessary. Recycle of concentrated chemical sludges to the rapid mix or flocculation basins can be accomplished to maximize phosphorus removal when the chemical coagulation is carried out in a separate step. The coagulant dose can be selected solely on the basis of phosphate removal rather than on the maximum dose compatible with the operation of the biological system.

At the Rondebult Sewage Purification Works at Germiston, Transvaal, South Africa, underground mine water with a high Fe- content was used for PO_4^{3-} removal from sewage effluents to comply with the recently enacted limit of 1 mg/l for the greater Witwatersrand area. VAN DER MERWE, et al. (1983) reviewed the theory of Fe phosphate precipitation and refer to other phosphate removal plants in Wisconsin. The addition of Al and Fe salts does not seem to harm biological life on the filter. The dosing of iron in acid mine drainage appeared to inhibit nitrification and reduce the pH increase through the filters and increase the total dissolved solids in the effluent by about 500 mg/l. An equivalent dosage of 20 mg Fe/l maintained the final phosphorus level at 0.1 cents/m^3 which is only 10% of the cost if $FeCl_3$ had been added as a chemical.

Additional information could be requested from:

P. H. VAN DER MERWE
Rondebult Sewage Treatment Plant
Germiston Municipality
Germiston, Transvaal
South Africa

The National Institute for Water Research, CSIR in Pretoria has also experimented with the addition of ferric chloride for phosphate removal. Their Dr. Lucas R. J. van Vuuren has experimented with lime coagulation.

The NIWR experience indicated that dosages of two to three times the stiochiometric requirement are needed to efficiently reduce phosphates below the 1 ppm limit.

Experiments at Boksburg and the Pretoria Dasspoort Experimental Sewage Plant indicated that the flocs are very light and difficult to settle. Polyelectrolytes were needed to

improve flocculation and settling. The use of polyelectrolyte flocculant alone without the metal containing coagulant results in an extremely fine precipitate which will not settle.

NIWR also experimented with the addition of $FeCl_3$ to the septic end of the sewage plant without success. $FeCl_3$ applied ahead of the primary sludge settling step flocculates out many other species including some organic compounds which helped to reduce the load on the biofilter. They found $FeCl_3$ almost ineffective in removing polyphosphates unless they are bonded to carbon on the suspended solids.

Based on their experiments, the NIWR concluded that it would be best to add $FeCl_3$ at two points--first ahead of primary settling, and then again after the polyphosphates have been hydrolized. The settled sludge goes to digestors in which $FePO_4$ is stable. Ultimately, after the trickle filter step, a humas tank settler is installed where residual phosphate is settled out more efficiently if dosed with $FeCl_3$.

The NIWR pointed out that if $FeCl_3$ is added, the extra chloride added will present a problem on the Witwatersrand where chloride and TDS levels are already building up in the Vaal Dam. Typical does of $FeCl_3$ to sewage would be 100-150 mg/l to be effective.

In South Africa, the major supply of $FeCl_3$ is from KOP who produce $FeCl_3$ from steel pickle liquors. However, $FeSO_4$ in ISCOR pickle liquor can be used as readily, or Al salts can be used instead of iron salts. In this respect, the VAN DER MERWE (1983) idea of using acid minewater containing iron may be a good one near mine-mill installations where such water is available.

NIWR point out that most metal-PO_4^{3-} compounds agglomerate best at relatively narrow pH ranges. $FeCl_3$ works best at pH 4-6 so for sewage at pH 7.5, an increased dose of $FeCl_3$ is necessary.

It is believed that the Boksburg Municipal Sewage Works on the eastern Witwatersrand uses $Fe_2(SO_4)_3$ to precipitate and coagulate phosphate which is more desirable because it adds $SO_4^{=}$ rather than Cl^- to the product water.

It was mentioned that the Rand Water Board uses activated silica for phosphate removal by coagulation, and reference was made to Mr. S. W. Van der Merwe at the Vereeniging Water Treatment Plant, also located near Johannesburg.

Research into phosphate removal processes is being conducted by the Johannesburg City Engineer's Department: Mrs. Lorraine Lotter, Johannesburg, telephone (011) 728-7373.

A Witwatersrand company, Prentec (Pty) Ltd., offers small package phosphate removal plants which employ coagulation with $FeCl_3$. These plants are suitable for communities such as mines of up to 3,000 people. They are prepared to guarantee a 1 ppm maximum limit for phosphorus in the phosphate form.

PRENTEC (PTY) LTD.
Post Office Box 1433
Edenvale 1610
(011) 609-5216
John A. Buchanan

At Vaal Reefs Exploration and Development Co. operations on the western Witwatersrand, an iron-rich uranium plant raffinate was effectivly used to remove phosphate from sewage effluents. Raffinates are low in pH and contain high concentrations of $Fe_2(SO_4)_3$. This worked well as long as the uranium plant was using ferric ions as an oxidant. When the U-plant switched back to using manganese dioxide as an oxidant, the manganese levels increased in the raffinate to an extent that the raffinate could no longer be added to sewage without causing a manganese problem when the effluent was discharged.

BIOLOGICAL PHOSPHATE REMOVAL

Bacterial processes for phosphate removal include the conventional activated sludge process, biofiltration (trickle filters), and the more sophisticated patented Bardenpho and Phoredox processes. Some of these have been discussed in MATLOCK (1978) but since then, there have been the major new developments in the Badenpho and Phoredox processes.

Typical average feed concentrations for settled sewage and raw sewage from a mainly residential community such as a mining camp would be as follows:

	Settled Sewage				Raw Sewage			
	COD	Total P	TKN	NH_4-N	COD	Total P	TKN	NH_4-N
Maximum (ppm)	359	6.6	36.6	24.5	394	5.4	35.6	22.2
Minimum (ppm)	148	3.3	16.8	12.4	338	4.9	31.5	22.6

The following paper lists several activated sludge plants including the "new" Stilfontein plant which is a five-stage Bardenpho Mark III plant designed in 1977 and described in a trip report in Appendix I.

According to Mr. P. J. Pybus of Stewart, Sviridov and Oliver, the Bardenpho plant installed at Windhoek does a good job of removing ammonia to less than 0.5 ppm but is not effective in removing PO_4^{3-}.

BIOLOGICAL PHOSPHATE REMOVAL - PLANTS

The University of the Orange Free State in Bloemfontein, South Africa, has investigated the use of marsh vegetation as a means of purifying acid mine drainage. At least one Ph.D. thesis has resulted, showing that bullrushes in the volunteer marshes that are found in acid mine drainage affected areas do exhibit seasonal phosphate uptakes. More information on his research can be obtained from:

Water hyacinths are believed also to remove some phosphate from effluents as well as to remove heavy metals, but these grow only in very warm subtropical water.

SCHWARZ (1983) discussed water reclamation by aquaculture, and his paper may include a discussion on phosphate removal.

The PHOREDOX process falls within the ambit of the Bardenpho patent No. 72/5371 and hence it has been necessary to protect the marketability of the latter by deleting detailed and explicit design information from the main text. The latter information may be obtained by arrangement with the patent holders, Messrs SAIDCOR, at PO Box 395, Pretoria. Further detailed advice regarding application of the design principles under specific circumstances as well as guidance on problems which may arise may be obtained from the NIWR.

CHAPTER 1

INTRODUCTION

In urban and industrial areas throughout the world, the demand and usage of water, and consequently the production of wastewaters, are rapidly increasing due to the population increase and the fact that in the civilized world the use of water has become inseparable from our industrial and domestic way of life. With the introduction of the Water Act in 1956 the previously disallowed practice, of direct discharge of sewage treatment plant effluents into the water courses, was permitted, provided the effluent met the required standard. With the increase of industrial activity in South Africa and the number of people linked to waterborne sanitation, rivers could no longer cope with increasing nutrient loads, particularly nitrogenous and phosphorus compounds, resulting in the enrichment of impoundments. In 1975, approximately 11 % of 98 impoundments studied, including most of the major dams in the country, were heavily eutrophic (i.e. excessively enriched), while approximately 40 % contained nutrient concentrations higher than was considered desirable (Toerien, Hayman and Bruwer, 1975). Effluents from sewage treatment works have been identified as a major contributor to eutrophication and it was realised that nutrient removal from this source, prior to discharge into natural water courses, would be necessary to alleviate this problem.

Ammoniacal nitrogen, apart from its inherent toxicity, is the nutrient which can most immediately cause problems in receiving waters, since the oxidation of ammonia to nitrate can deplete the dissolved oxygen in the water mass, which may lead to the death of both plant and animal life. This problem can be overcome by oxidizing the nitrogenous compounds in the wastewater to nitrate during the treatment process. This, in turn, may lead to undesirable side-effects such as high nitrate concentrations, which are costly to reduce chemically, and injurious to the health of babies, if ingested.

Enrichment of impounded waters can lead to some undesirable results, the primary effect being the accelerated and uncontrolled growth of various strains of algae, water grasses and both rooted broad leaved water plants and floating plants such as water hyacinth and Kariba weed. The prolific growth of these plants may prevent efficient oxygenation of water, causing the hypolimnion to become anaerobic.

Algae which proliferate in eutrophic waters may result in the formation of an unsightly algal scum. Wind-blown deposits on the shoreline are not only unsightly but cause a revolting smell as decomposition occurs. Some strains of algae are toxic to animal life, causing serious problems to farmers who water their stock at impoundments infested with these trains.

Secondary undesirable effects of eutrophication, result from the first and are the upsetting of the social amenity value of the impoundment and the complication of water purification processes. A great deal of money has been invested in developing and utilizing dams and rivers for recreational purposes. By allowing these resources to become eutrophied, their value is seriously limited causing a loss of revenue to resort owners, while individuals who enjoy boating and sailing are unable to utilize their equipment.

Occurrence of algae in water serving as a source for water supply, demands more complex purification treatment and increased plant maintenance, for example, sand filters will require more frequent backwashing.

Control of the nutrient content in effluents is important in areas where eutrophication has occurred or is likely to occur. The Department of Water Affairs (Rudd, 1979), has pinpointed such sensitive areas where control of the nutrient concentration in effluents is likely to be introduced:-

(a) The Vaal River from its catchment area to Bloemhof Dam.

(b) The upper Limpopo – Crocodile catchment including the catchment areas of the following dams: Rietvlei, Hartbeespoort, Roodeplaat, Klipvoor, Bon Accord, Vaalkop.

(c) The Great Olifants River above the Loskop Dam.

(d) The Umgeni catchment except where effluents discharge directly into the estuary or sea.

(e) The Umlaas River.

(f) The Buffalo River from King William's Town to Bridle Drift Dam.

(g) The Great Berg River.

(h) Atlantis.

In natural waters algae require a nitrogen:phosphorus ratio of 15:1, but since this ratio is approximately 4:1 in wastewater treatment plant effluents, it would seem that nitrogen should be the limiting nutrient. However, due to the nitrogen-fixing capability of various algal species it has been shown that in most cases phosphorus is the limiting nutrient (Toerien *et al* 1975). The removal of phosphate-containing compounds is therefore of prime importance when considering treatment methods aimed at limiting eutrophication.

Local authorities in these sensitive areas may be faced with problems of nutrient removal with existing plants or in proposed new works. There are a number of alternatives available for the control of effluent concentrations of phosphate, namely chemical precipitation, biological-chemical techniques and purely biological means. Chemical precipitation is normally used in exist-

ing plants to upgrade the effluent quality, usually by chemical addition to the plant effluent. In biological-chemical applications, the biological ability to remove phosphate is complimented by the addition of chemicals in order to reduce the effluent phosphate concentration to within acceptable limits. Biological processes achieve nutrient removal without the addition of possibly expensive chemicals, consequently the cost of the chemicals and the handling and disposal of an additional chemical sludge are avoided.

This technical guide will be concerned with the removal of phosphate by biological means only. The specific process considered is the Phoredox process, a biological nutrient removal process developed by the National Institute for Water Research, Council for Scientific and Industrial Research, South Africa. This process has been developed to remove both nitrogen compounds and phosphate from the discharged effluent stream. It is an extension of the patented Bardenpho process which was designed to remove the nitrogen compounds only.

The Phoredox process has been tested extensively on pilot plant scale by the National Institute for Water Research, at a Pretoria sewage works. The results are sufficiently promising that design engineers should seriously consider this process for biological nutrient removal. However, the designer must realize that the research into biological nutrient removal is by no means complete and throughout the world researchers are endeavouring to develop general descriptive equations for the kinetics of activated sludge. It is probable that even more efficient and economical processes will be developed for the biological removal of nutrients from wastewaters in the future.

CHAPTER 2

PROCESSES FOR BIOLOGICAL NUTRIENT REMOVAL

The Phoredox process described in this guide achieves nitrogen and phosphate removal without the addition of chemicals. The concept of biological nitrogen removal is not new and many attempts have been made to ensure consistent and reliable performance of nitrification and denitrification in activated sludge plants. A vast amount of literature is available dealing with the basic kinetics of these reactions. A brief summary follows on some of the major developments which have a bearing on this design guide.

Wuhrmann (1957, 1960) and Ludzack and Ettinger (1962) were amongst the earlier researchers who proposed activated sludge process configurations for nitrogen removal. Wuhrmann (1957) proposed a single sludge two-stage process with the sewage fed into an aeration stage together with the recycled sludge from the clarifier (Figure 1). The nitrified mixed liquor passed from the aeration stage to an anoxic stage, (no measurable dissolved oxygen), where denitrification occurred at a very slow rate due to low residual carbonaceous energy. This problem was overcome by introducing a nitrogen-free source of biodegradable organic carbon, such as methanol, thereby allowing a small, more efficient denitrification stage to be designed.

Ludzack and Ettinger (1962) placed the anoxic stage in front of the aeration stage (Figure 2), and created an internal recycle from the aeration stage into the anoxic stage by way of a notch weir in the separating baffle. The mixed liquor found its way back into the aeration stage through a slot provided between the baffle and the tank bottom. The feed sewage was introduced into the anoxic stage and the recycled sludge was returned to the aerated stage. The nitrate entering the anoxic stage was rapidly reduced in the presence of the incoming feed and the nitrate-free underflow was then introduced into the aeration stage where nitrification occurred. By increasing the recycle rate the nitrate concentration in the effluent could be reduced. This configuration resulted in high rates of denitrification without the use of an additional carbon source. For more extensive details on the development of the nitrification and denitrification processes the reader is referred to the publications of Sharma and Ahlert 61977) and Christensen and Harremoës (1977).

The first report of phosphate removal by an activated sludge process dates back to 1943 when Jenkins and Lockett (1943) noted that of the phosphorus entering a treatment works only 54 % was discharged in the effluent. Srinath, Sastry and Pillai (1959) performed the first detailed laboratory analysis of the ability of the activated sludge process to remove phosphate. Further investigations on the metabolic uptake of phosphate in an activated sludge process were reported by Levin and Shapiro (1965). The research indicated that activated sludge was able to remove more phosphate than was required for normal growth, and the term 'luxury uptake' was introduced to describe this mechanism. They were granted patent rights (Levin, 1964) on the 'Phostrip' process in 1964 and the process has proved to be successful both at pilot plant (Levin, Topol, Tarnay and Samworth, 1972), and full-scale application (Levin, Topol and Tarnay, 1975). The 'Phostrip' process (Figure 3) consists of an activated sludge reactor into which recycled sludge is introduced with the influent feed. In the earlier plants no provision was made for the removal of nitrogen, but a subsequent patent (Levin, 1972) was granted covering the removal of nitrogen. The activated sludge reactor is designed to handle the carbonaceous oxidation, nitrification and denitrification following the system proposed by Wuhrmann (1957). The outflowing mixed liquor enters a settler where the activated sludge solids are settled and the supernatant discharged. The solids are passed to a second, anaerobic clarifier where, in the absence of both dissolved oxygen and nitrate, phosphate is released from the organisms into the supernatant of this clarifier. The phosphate-'stripped' sludge is returned to the activated sludge reactor while the phosphate-enriched secondary supernatant is treated with lime, to precipitate the phosphate. This process is capable of producing an effluent with a very low phosphate concentration but achieves relatively poor denitrification, unless an external carbon source is introduced into the anoxic stage. Full-scale biological phosphate removal has been reported by Vacker, Connell and Wells (1967), at the municipal wastewater treatment plant at San Antonio, Texas. The plant consisted of three modules operated in parallel and fed with the same influent feed. By varying the form and degree of treatment they were able to observe what parameters were correlated to effective phosphate removal, while each module was operated within the limits of maximum BOD removal. Based on this study the author concluded that under conditions of limited nitrification, 'luxury' metabolic uptake occurred. In terms of more recent thinking, the successful removal of phosphate may be attributed to the limitation of nitrate which allowed the process to become anaerobic, most likely in the clarifier, and as a consequence of this the biological sequence for phosphate uptake was supported.

With regard to the basic procedure of phosphate removal, two schools of thought soon developed. On the one hand was the theory of chemical precipitation as outlined by Menar and Jenkins in 1970, and later modelled by De Boice and Thomas (1975). On the other there was the biological uptake theory, described as 'luxury' uptake or 'enhanced' removal. The chemical precipitation theory holds that the biological incorporation of phosphate into the organisms, in an activated sludge mass, results in a maximum of approximately 2 % by mass of phosphate (as P). Phosphate

FIG. 2: The Ludzack-Ettinger process for biological denitrification

FIG. 3: Schematic flow diagram for the Phostrip process

concentrations, determined from sludge, which are in excess of this normal 2 % is caused by chemical precipitation of phosphate by the natural metal ions abounding in the carrier water mass. The pH of the mixed liquor was found to increase significantly from the point of entry to the point of exit, due to the stripping of carbon dioxide. This pH change was thought to be instrumental in causing the phosphates of calcium and magnesium to precipitate.

The researchers supporting the biological or 'luxury' uptake theory, were not able to propose a basic concept of the mechanisms of removal, but reported that when there was significant phosphate uptake during aeration, there were frequently higher concentrations of phosphate in the effluent from the secondary clarifier. This increase in phosphate concentration was thought to be caused by oxygen deficiency or low redox potential during settling. (Shapiro, Levin and Zea, 1967).

The publication of the chemical precipitation hypothesis prompted further research into the possible mechanism of phosphate removal and Yall, Boughton, Knudsen and Sinclair (1970) reported, after having used radio-active phosphorus (^{32}P) and also an inhibitor (2,4-dinitrophenol) to biological oxidative phosphorylation, that there was no doubt that the uptake of phosphate was mostly biological in nature. The authors concluded that much of the phosphate taken up by the sludge is associated with a mechanism involving the synthesis of adenosine triphosphate (ATP). More recently Carbury and Tenney (1973) re-examined the possibility of biological uptake, using much the same techniques as the previous researchers, and reported that their findings indicated that the removal of phosphate occurred by biological uptake. The authors indicated that the two possible mechanisms by which phosphate could be transported into the cell could be either a diffusion-controlled mechanism driven by a positive concentration gradient between the outside and inside of the organism cell, or an active transport mechanism in which energy derived from metabolic processes inside the cell drives the transport into the cell against a negative concentration gradient. Morgan and Fruh (1974) ran experiments using synthetic substrates which precluded chemical precipitation and reported that their results indicated that a 'luxury' uptake of phosphorus by activated sludge is not the exception, but the rule.

Further evidence supporting the biological uptake theory was provided by Fuhs and Chen in 1975. These authors used sludge taken from Baltimore, Maryland, to conduct a number of microbiological laboratory experiments from which they concluded that the opinions of Levin and Shapiro (1965) were valid but that the biological uptake of phosphates was caused essentially by a single strain of micro organism, namely *Acinetobacter* although uptake by other organisms was not ruled out. The role of the anaerobic stage was examined and they concluded that this stage supported the growth of organisms which tend to produce components such as ethanol, acetate and succinate which serve as a carbon source for *Acinetobacter*.

Barnard, in 1973, reviewed the available technology for biological nitrification and denitrification and as a result of this work proposed a four-stage reactor based on the principles originally introduced by Ludzack and Ettinger (1962) and Wuhrmann (1957). This proposed process was tested on pilot plant scale under ambient temperature and variable sewage composition conditions. The Council for Scientific and Industrial Research was granted patent rights (72/5371, 1973) for this treatment process, which has subsequently become known as the Bardenpho process (Figure 4). The system, as patented, consists of four stages – primary anoxic, primary aerated, secondary anoxic and secondary aerated, followed by a clarifier. During further studies there emerged one necessary precondition to the removal of phosphates in the activated sludge system. This condition is that the mixed liquor or the return sludge from the clarifier underflow must go through a period of anaerobiosis such that phosphate is released to the liquid, followed by a period of aeration during which the phosphates would be either precipitated or adsorbed by the sludge mass (Barnard, 1975). Both laboratory and pilot plant scale work was undertaken to substantiate this postulate and from this work has developed the Phoredox process, a process which is specifically designed to remove both nitrogen and phosphate from sewage. This modified process consists of five stages – the Bardenpho sequence with

FIG. 4 Schematic flow diagram for the Bardenpho process

FIG. 5: **Schematic flow diagram for the Phoredox process**

an additional stage, the anaerobic stage, placed at the head of the process (Figure 5). Into the anaerobic stage is fed the influent sewage feed and the sludge recycled from the clarifier underflow. The outflow from the anaerobic stage is passed into the primary anoxic stage into which also flows the mixed liquor recycle. The mixed liquor recycle is drawn from either a position within the primary aeration stage, which is the third stage of the process, or from the outflow from this aeration stage. The remainder of this outflow enters the secondary anoxic stage which is followed by the secondary aeration stage and finally the clarifier, from which the supernatant liquor is discharged and the settled solids are returned to the head of the process.

CHAPTER 3

THE PHOREDOX PROCESS

The Phoredox process is a five-stage process (Figure 5) designed to remove nitrogen and phosphorus by biological means. The functions of nitrification-denitrification and phosphate release-phosphate uptake, are two entirely separate reactions which proceed side by side in the same reactor. In order to achieve optimum performance in a plant it is most important to have a clear understanding of these reactions and the conditions which best support them. To this end the process will be considered stage by stage and the reactions occurring in these stages will be described as far as present day knowledge allows. The concentrations quoted in the following explanation are typical for a plant which is operating well. Since the feed quality is usually found to vary under normal operating conditions, there are factors which may render the process less efficient. These will be outlined later.

ANAEROBIC STAGE

The activated sludge underflow from the clarifier is pumped into this, the first stage of the process, together with the influent sewage feed (Figure 5). It is of great importance that the concentration of dissolved oxygen should be kept as low as possible in this recycle, preferably less than 1 mg/ℓ. Since the sludge leaving the clarifier has either no dissolved oxygen, or in any event a very low concentration, the concentration of dissolved oxygen entering the anaerobic stage is entirely dependent on the design of the recycle and its inherent ability to avoid oxygen entrainment. When the recycled sludge and the feed are mixed on introduction into the anaerobic stage, any dissolved oxygen present is first utilized followed by the reduction of nitrates principally to nitrogen gas. As soon as the nitrates have been reduced conditions described as 'anaerobic' exist, and soluble phosphate is released into the aqueous phase (Figure 6).

This observed release of phosphate is a basic requirement before successful phosphate uptake in the third stage (Figure 5) of this process can occur. There is, apparently, a lower limit of phosphate release below which the subsequent uptake progressively deteriorates. It is, therefore, most important that sufficient retention time be provided, to allow for the minimum phosphate release to be attained under the most adverse conditions, that is either high nitrate input in the sludge recycle or low feed COD input. A high nitrate (as N) concentration is considered to be above 6 mg/ℓ while a low COD is below 250 mg/ℓ. The retention time for this basin is empirically related to the primary anoxic rate of denitrification. The anaerobic retention time should be sufficient for the reduction of the influent dissolved oxygen and nitrate concentrations and provide for an additional period equivalent to at least 15 mg/ℓ of nitrate. This extra period amounts to about 1¼ to 1½ hours nominal retention time at 20 °C.

FIG. 6 Denitrification and phosphate release in the anaerobic stage

PRIMARY ANOXIC STAGE

The mixed liquor discharged from the anaerobic stage usually contains 0,5 mg/ℓ nitrate (as N) or less, and a high concentration of phosphate, depending on the influent COD concentration, phosphate concentrations between 10 mg/ℓ and 25 mg/ℓ (as P) may be expected. These values are approximately 1,5 to 3 times greater than the influent feed total phosphate concentration. The concentration of soluble COD is usually of the order 25 mg/ℓ to 35 mg/ℓ. This mixed liquor is passed into the second stage which is known as the 'primary anoxic' stage, the principal purpose of which is the denitrification of nitrates in the recycled mixed liquor from the primary aeration stage. The mass of nitrate reduced by denitrification is proportional to the rate of recycle, up to the point when nitrate starts to appear in the effluent leaving this anoxic stage. The mass of nitrate removed is also influenced by the dissolved oxygen introduced into this stage in the mixed liquor recycle drawn from the primary aeration stage. Denitrification will commence only after the dissolved oxygen concentration has been reduced to zero, and the process will then continue either until the available nitrate has been depleted or until the mixed liquor leaves this stage and enters the primary aeration stage. If denitrification is complete within the anoxic retention time, anaerobic conditions will be created in which phosphates will further be released. Experience has shown that this additional release is not detrimental to efficient phosphate uptake and is therefore not a condition which has to be prevented. If denitrification is not complete before the mixed liquor leaves this stage, the remaining nitrate will be re-introduced into the primary aeration stage, generally leading to higher concentrations in the effluent. The concentration of phosphate (as P) in this stage is greatly influenced by the magnitude of the mixed liquor recycle. Due to the dilution effect of this recycle, values of between 5 mg/ℓ and 10 mg/ℓ (as P) are usually measured. These values range from 1 to 1,5 times the concentration of total phosphates found in the influent feed.

PRIMARY AERATION STAGE

The primary aeration stage is the principal site for the oxidation of biodegradable nitrogen and carbonaceous matter. The reactions are supported by providing surface aerators or submerged diffusers of sufficient capacity to deliver the required mass of oxygen. This stage is designed to provide a retention time long enough to ensure the required reduction in organic nitrogen concentration. If there is any unoxidized carbonaceous matter in the mixed liquor leaving this stage, it is to the benefit of the denitrification which occurs in the fourth stage, namely the secondary anoxic stage. It is during this aeration stage that the reduction in phosphate concentration occurs. Diurnal peaks in carbonaceous, nitrogenous and phosphorus loading as well as the phosphate released in the anaerobic stage occur together. Since the capacity of the aerator is designed for an average value, it may be found that during the periods of these peaks the concentrations of unoxidized organic nitrogen, ammonia and phosphates will be increased in the mixed liquor leaving this stage. The dissolved oxygen concentration should be maintained in the vicinity of 2 mg/ℓ, even though concentrations below 1 mg/ℓ are sufficient to indicate that there is enough oxygen to support the oxidative processes. It has been found experimentally that the dissolved oxygen concentration can be limiting if maintained too low. With submerged diffusers it has been found that, at dissolved oxygen concentrations of approximately 1 mg/ℓ, the uptake of phosphates was not satisfactory, while at the suggested concentration of 2 mg/ℓ the removal was good.

The rate of the mixed liquor recycle, from the primary aeration stage to the primary anoxic stage, is controlled to obtain the desired reduction in nitrates. The recycle rate is calculated from the denitrification potential of the primary anoxic stage. It is desirable to provide capacity to vary this recycle rate from the design value, in order to cater for sewage characteristics which differ from those originally considered, an eventuality which may well occur during the useful life of the plant. When designing the primary aeration stage, the possibility of being able to increase the primary anoxic retention time, at the expense of aerated retention time should be considered. If the daily sewage feed concentrations vary significantly, (a situation which occurs when industrial effluents form part of the sewage feed) the primary denitrification efficiency may decline. Under these circumstances it is very useful to be able to extend the anoxic retention time, in order to maintain a satisfactorily low concentration of nitrates in the effluent. Under these conditions, the reduction of aeration capacity is unimportant since the process requires a reduced oxygen input. This procedure may be adopted up to the point where the growth of the nitrifying organisms is inhibited. To reduce the aerobic retention time further than this point will cause an increase of ammonia in the final effluent.

SECONDARY ANOXIC AND AERATED STAGES

The mixed liquor entering the secondary anoxic stage contains approximately 25 mg/ℓ soluble COD, 1 mg/ℓ phosphate (as P), usually less than 1 mg/ℓ organic nitrogen (as N) and zero, or nearly zero, ammonia concentration. The concentration of nitrates, depending on the mixed liquor recycle, will usually be between 6 mg/ℓ and 10 mg/ℓ (as N). The main purpose of this stage is to reduce the nitrate concentration to as low a value as possible, bearing economics in mind. The rate of denitrification in the fourth stage is low as the energy supporting the process is derived from the decay of organisms which release carbonaceous matter that can be utilized by the surrounding surviving cells. Since the rate of denitrification is low, a long retention time is required before a significant decrease in nitrate concentration is achieved. In general there is no change noted in the phosphate concentration as a result of this stage.

The secondary aeration stage is included in order to reaerate the mixed liquor prior to its entry into the clarifier. The introduction of this stage provides an additional safeguard to prevent the onset of anaerobic

conditions in the clarifier which would cause phosphate release, resulting in unnecessarily higher phosphate concentrations in the plant effluent. The concentrations of phosphates and nitrates are generally not altered in the secondary aeration stage where the retention time is both short and selected empirically. If there is a residual ammonia concentration leaving the primary aeration stage it will be oxidized to nitrate in this stage, causing a small increase in the nitrate concentration.

CLARIFIER

The separation of solids from the treated aqueous phase is as important an aspect of the treatment operation as the activated sludge reactor. If the separation is poor the final effluent will have a high concentration of suspended matter and as a consequence the concentrations of phosphate and COD will be proportionately higher. Without an efficient recycle of solids back to the activated sludge reactor a breakdown in the system is certain. It is, therefore, essential that the phase separation should produce an effluent low in suspended solids and a thickened solids mass which can be recycled. The separation process may be achieved by using any suitable phase separation process, with the exception of dissolved air flotation which would cause the solids recycle to the anaerobic stage to contain large concentrations of dissolved oxygen causing serious operational problems. The sedimentation type of clarifier is usually selected and in the design of this unit it is important to consider the quality of sludge produced by the Phoredox process.

The relatively long time that the mixed liquor is maintained in anaerobic or anoxic conditions may be responsible for the production of a sludge which has variable settling characteristics. Sludge volume indexes (SVI) determined from unstirred settling tests are usually in the range 300 – 400, at times decreasing to 150. These values would normally indicate a sludge that is quite unacceptable. However, experience has shown that this test does not provide a true reflection of the sludge characteristics. Pitman (1978) examined sludges produced by biological nutrient removal plants and when comparing them with sludges produced in different processes, concluded that the sludge age and the degree of aeration are very important considerations in generating a sludge with good settling properties.

In Pretoria, the pilot plant sludge was found to be rather filamentous, a state which seems to be common with the Phoredox process. Consequently it is advised that clarifiers should be designed with a view to poor settling properties. If, in operation, sludge loss occurs, the matter can be counteracted by increasing the limiting flux condition which is achieved by increasing the sludge recycle rate. This procedure is effective only when sludge thickening is the problem. If clarification cannot be obtained, increasing the recycle rate will achieve nothing and solids will be lost until the reactor mixed liquor solids concentration is sufficiently reduced to achieve an improved settling velocity. It is important to provide reserve pumping capacity in order to allow operational flexibility.

WASTE SLUDGE HANDLING

Sludge wasted from the Phoredox process may be applied directly to drying beds, or as is more usual, it may first be thickened. Pilot plant tests indicate that mixed liquor wasted from the primary aeration stage can be thickened from approximately 3 000 mg/ℓ to approximately 18 000 mg/ℓ in 5 to 6 hours. The thickened sludge required between 3 and 5 days to dry on a bed of coarse river sand. A full scale application of this method of sludge handling, at Windhoek, Namibia, produced results very similar to those found in Pretoria.

When designing a waste sludge drying bed system, there are two important factors to consider. Firstly, the supernatant from the thickener and secondly, the water percolating through the drying bed, must receive special attention. In the thickener, due to the extended retention time, anaerobic conditions will occur leading to the release of phosphate, resulting in a supernatant with high concentrations of phosphate. The water percolating through the drying beds will have very high phosphate concentrations and therefore an efficient sealed drainage system is required.

The water containing high phosphate concentrations must then be handled such that the phosphate is denied access to natural waters. A possible solution is to remove the phosphate by chemical precipitation. With the volume of water to be treated being relatively small, the required size of the treatment facility will be minimal.

CHAPTER 4

PILOT PLANT EXPERIENCE OF BIOLOGICAL NITROGEN AND PHOSPHORUS REMOVAL

The operating criteria outlined in the following paragraphs were obtained by operating a pilot plant designed for biological nitrogen and phosphorus removal, using the principles outlined in the previous chapter. The initial design of the process was not altered significantly for a period of over two years, thereby allowing a long-term analysis to be made of the efficiency of the Phoredox process. The results of this analysis are included to indicate, in real terms, what can be achieved with this process and, probably of greater importance, some of the problems encountered under near practical conditions.

TABLE 1
Volumes of the stages

Stage	Volume
Primary anaerobic	10.08 m³
Primary anoxic	10.56 m³
Primary aerated	26.58 m³
Secondary anoxic	20.88 m³
Secondary aerated	5.28 m³
Total	73.38 m³

PILOT PLANT SPECIFICATIONS

The pilot plant (Figure 7) consisted of 16 corrugated iron tanks and a settlement type rim flow clarifier of 12 m³ capacity. The effective volumes of the various tanks (or basins) were accurately determined under operating conditions (Table 1).

Positive displacement pumps were used for the feed, and the sludge recycle from the clarifier, and a centrifugal pump for the mixed liquor recycle. These three flows were controlled by means of separate penstocks (Figure 7). The feed was metered through an orifice while the sludge recycle and the mixed liquor recycle were controlled through triangular weirs. Both the weirs and the orifice were calibrated, practically, in order to determine their respective discharge coefficients. The measurements showed that the flow was determined to within an accuracy of 1,5 %.

Every basin was stirred with the exception of the secondary aerated basin (2N). Air was supplied by means of a blower through a pattern of submerged porous dome diffusers. The dissolved oxygen concentration was controlled between 2 mg/ℓ and 3 mg/ℓ by connecting an oxygen-sensitive probe, in the first basin

FIG. 7 Pilot plant (100 m³/day) used to study biological phosphate removal

of the primary aeration stage (1N1), to a meter which was set to activate a relief valve in the blower air line. The dissolved oxygen in the other aerated basins was controlled by butterfly valves in the air supply pipes.

The volume of sludge wasted was drawn off the last basin of the primary aeration stage (1N5) and allowed to flow into the waste tank under gravity, through a partially opened valve. This ensured a very slow flow rate which did not upset the plant flow unduly. The waste tank filled to the hydraulic level of 1N5 and thus a precise volume of 4,93 m^3, was wasted each day. Sludge wasting was performed every day except on rare occasions when the feed had been off for a long time or sludge was lost because of a breakdown.

The sludge age, defined as:

$$R_s = \frac{\text{Volume of mixed liquor in the reactor}}{\text{Volume of mixed liquor wasted per day}} \quad \ldots\ldots 4.1$$

was therefore maintained at an average value of:

$$R_s = \frac{73,38}{4,93} = 14,9 \text{ days.}$$

PILOT PLANT OPERATION

The pilot plant was designed to treat 100 m^3/d of feedstock, with a sludge return recycle rate of 100 m^3/d, the mixed liquor recycle from the primary aeration stage to the primary anoxic stage being 400 m^3/d. This latter recycle was later reduced to 200 m^3/d.

From the volumes of the stages (Table 1) and the flow rates given above, the nominal and actual retention times may be calculated and are given in Table 2.

TABLE 2

Pilot plant nominal and actual retention times for sludge recycle ratio (s) = 1, and for mixed liquor recycle (a) = 4 or 2

Stage	Retention time (min)		
	Nominal	Actual at 4:1	Actual at 2:1
Anaerobic	145	73	73
Primary anoxic	152	25	38
Primary aerated	380	113	133
Secondary anoxic	300	151	151
Secondary aerated	76	38	38
Total	1056		

The pilot plant was operated for a little more than two years of which the first 16 months were spent treating settled sewage obtained from the Pretoria Municipal Treatment Works, Daspoort. The settled sewage was piped from the primary clarifiers and introduced into the pilot plant without any further processing. The wastewater treated comprised approximately 80 % domestic sewage and 20 % from industrial contributors, including the municipal abattoir, a brewery and a dairy. In order to simplify the control of the feed pump, the sewage feed rate to the plant was kept constant. There were, however, diurnal variations for chemical oxygen demand (COD), total Kjeldahl nitrogen (TKN), and total phosphate (Figure 8). The decision to use settled sewage was made because it was thought that the process conditions would be made more difficult due to the less favourable COD:TKN and COD:(total phosphate) ratios in settled sewage, while maintaining a relationship to practical treatment conditions. At the same time

FIG 8 Diurnal variations of COD, TKN and total phosphate concentration

operational reliability was assured by eliminating the problem of pump blockages due to large particulate matter. Following this period of treatment the feed was altered and settled sewage was replaced by raw sewage. The sewage received from the municipality was screened through a wedgewire screen, the gaps between the screen wires being 0,2 mm, in order to protect the feed pump from rags, paper and other solid particles which would have caused damage. The introduction of this screen was very successful in removing solids but the collection of grease and oil from the sewage caused the screen to become less and less efficient. The problem was relieved by introducing a compressed air blower, and by chemically cleaning the screen once a week. The plant was operated for six months using raw sewage after which the feed was changed back to settled sewage.

The monthly mean feed concentrations for COD, TKN and total phosphate (as P) are given in Table 3.

TABLE 3
Monthly average feed concentrations for settled sewage and raw sewage (mg/ℓ)

	Settled sewage				Raw sewage			
	COD	Total phosphate	TKN	NH_4-N	COD	Total phosphate	TKN	NH_4-N
Maximum	359	6.6	36.6	24.5	394	5.4	35.6	22.2
Minimum	148	3.3	16.8	12.4	338	4.9	31.5	22.6
Mean	271	5.4	28.5	19.9	369	5.4	33.4	21.4

ANALYTICAL PROCEDURES

A comprehensive programme of sampling was introduced. The samples taken from the clarifier (effluent) and the various basins were filtered, using Whatman No. 2 filter paper and analysed using auto-analytical methods. The feed samples were not filtered and analysed by manual procedures.

All samples taken for chemical analysis were preserved with mercuric chloride as soon after sampling as possible, or with sulphuric acid where the former method might have interfered with the required chemical determination.

OPERATIONAL RESULTS

COD Removal

The daily composite COD values for the influent are given in Figures 9 and 10. A weekly cyclic pattern emerged with low values on Sunday or Monday and considerably higher values for the remainder of the week (Figure 11). The removal of COD remained consistently good whether settled or raw sewage was treated. The average effluent COD concentration was 23 mg/ℓ, representing an overall removal efficiency of greater than 90 %. Filtered samples taken from the last basin of each stage indicated that the COD concentration did not vary from after the first stage – the anaerobic stage – indicating that the biologically degradable COD had been accepted into the solid phase of the mixed liquor. The removal of COD in the anaerobic

FIG. 9: Phoredox pilot plant performance

FIG. 10: Phoredox pilot plant performance

FIG. 11: Daily variations of influent and effluent COD, nitrogen and phosphate concentration

stage is thought to be due to adsorption. This process is very rapid to the point that samples taken immediately after contact between feed and return sludge averaged to give a filtered COD concentration of 32 mg/ℓ.

Nitrification — Denitrification

The daily effluent nitrate concentrations are presented in Figures 9 and 10, while the overall mean values for the period using settled sewage and raw sewage are given in Table 4.

The average concentration of total nitrogen in the effluent for the two periods was 6,1 mg/ℓ (as N) and 5,2 mg/ℓ (as N) for settled sewage and raw sewage respectively, of which approximately 1 mg/ℓ was organic nitrogen. These figures indicate that overall, more than 95 % organic nitrogen was oxidized to nitrate or utilized in cell synthesis and of the nitrate formed approximately 80 % was reduced by denitrification. The additional 36 % COD energy available in raw sewage reduced the effluent nitrate by a further 30 %, thereby providing conditions which should have been excellent for phosphate removal.

Phosphate Removal

The orthophosphate concentrations in the effluent are given in Figures 9 and 10, where a close relationship between nitrate concentration and phosphate concentration in the effluent is evident. These concentrations

TABLE 4
Monthly mean effluent concentrations for settled sewage feed and raw sewage feed (mg/ℓ), analysed from filtered samples

	Settled sewage feed					Raw sewage feed				
	COD	Ortho PO_4 P	NO_3 N	TKN	NH_4 N	COD	Ortho PO_4 P	NO_3 N	TKN	NH_4 N
Maximum	34	2.4	8.9	1.0	0.2	27	2.0	4.5	1.2	0.2
Minimum	15	0.5	3.9	0.7	0	24	1.0	4.2	1.0	0.1
Mean	23	1.2	5.2	0.9	0.1	23	1.7	4.0	1.2	0.1

rose regularly over weekends coinciding with the drop in COD (Figure 11). The process treating settled sewage was able to produce an effluent with an overall average of 1,2 mg/ℓ (PO_4-P) which included the high peaks experienced during the few breakdowns that occurred during the test period. However, the average value for the period when raw sewage was used was 1,7 mg/ℓ or 42 % higher. The poorer removal efficiency is also revealed when calculating the factor $\frac{P}{COD}$ (Table 5). This factor is calculated by dividing the difference between the mass of phosphate in the feed and in the effluent by the mass of COD removed. The resultant factor represents possibly the most accurate assessment of phosphate removal efficiency.

TABLE 5
Phosphate removal efficiency

Period	$\frac{\Delta P}{\Delta COD}$	% Removal of PO_4 P
Settled sewage feed	0.017	78 %
Raw sewage feed	0.011	58 %

No reason can yet be forwarded to explain this apparent paradox, but it would seem that primary clarification introduces a significant improvement in the phosphate removing process efficiency. The mean PO_4-P values would be greatly reduced if the weekend peaks, caused by poor denitrification, were removed. A method which seems to offer a satisfactory solution, is to increase the primary anoxic retention time by switching off aerators at the beginning of the primary aeration stage, thereby increasing the primary anoxic stage retention time but at the same time reducing the primary aeration retention time. This reduction is unimportant as the reduced COD input, causing poorer denitrification, itself requires less oxygen for its oxidation. However, as mentioned previously, if this process is taken too far, the growth of nitrifiers — which are obligate aerobes — will be inhibited causing the appearance of ammonia in the effluent. A further danger is the creation of suitable conditions for the proliferation of filamentous organisms. These organisms cause the solids to settle poorly in the clarifier, which may lead to sludge loss.

The relationship between COD, effluent nitrate and phosphate release can be seen in Figures 12 and 13. With a low effluent nitrate concentration (Figure 12) the release of phosphate closely follows the influent COD, and after an effective release the effluent phosphate is virtually absent. However, with high effluent nitrates (Figure 13) the release is suppressed, resulting in a marked increase in effluent phosphates.

Temperature

The liquid temperature ranged between 15 °C (winter early morning) and 26 °C (summer day) while ambient temperatures varied between 0 °C and 36 °C. Although the temperature range was 11 °C there was no apparent effect on phosphate removal. Since this test was run under natural conditions, it is not possible, at this stage, to report what effect temperatures lower than 15 °C might have on the pilot plant's efficiency to remove phosphate. The temperature dependencies for nitrification and denitrification had been established previously. During the period of operation of this plant the processes of nitrification and denitrification were satisfactory throughout, due to the fact that sufficient reaction time had been allowed for minimum temperature conditions.

Mixed Liquor Suspended Solids Concentration

The suspended solids concentration was relatively steady throughout the test. From Figure 9 two periods of instability are evident, the first was in March 1977 when lower average weekly COD values occurred due to rainfall; the second, in June 1977, was the result of faulty operation and mixed liquor was accidentally lost. In both cases the sludge concentrations returned to normal in approximately 1 sludge age, that is two weeks.

During the periods of recovery the volatile suspended solids (MLVSS) represented as much as 83 % of the mixed liquor suspended solids (MLSS), while normally it was of the order 75 %, indicating the presence of a greater proportion of new cells. After the change to raw sewage the MLSS reflected the rise in COD concentration by immediately increasing, and after a period

FIG 12 Diurnal influent COD and phosphate concentration in the anaerobic stage

FIG 13 Diurnal influent COD and phosphate concentration in the anaerobic stage

equal to approximately two sludge ages reached its maximum value. This was followed by a period of variability after which the concentrations of MLSS and MLVSS became very stable until the feed was changed back to settled sewage. The mean values for MLSS and MLVSS were:-

	MLSS	MLVSS
Settled sewage feed	2150	1648
Raw sewage feed	3167	2440

CHAPTER 5

DESIGN AND OPERATIONAL CONSIDERATIONS

The success of a Phoredox process does not depend on the process design only. In fact the translation of the process design into practical reality and the correct operation of the constructed plant are equally important.

DESIGN CONSIDERATIONS

In the layout of a reactor it is important to bear in mind that operational flexibility is a major asset to the plant operators. The recycle pumps should be sized such that there is reserve pumping capacity. It has been found that the settling characteristics of the sludge changed, resulting in a sludge which settled badly. In order to prevent sludge loss, experience has shown that by increasing the sludge recycle, and therefore the total flux in the clarifier, the sludge loss can be minimized. However, if the settling characteristics are so bad that clarification cannot be obtained, increasing the total flux will not make any difference. In this case solids loss will continue until the MLSS concentration in the reactor is sufficiently reduced to achieve improved settling characteristics. The design of the clarifiers, therefore, demands particular attention.

The method of aerating the mixed liquor in the primary aerator deserves careful consideration. With the use of surface aerators it is possible that anoxic, and possibly even anaerobic zones may result in the aeration basin due to the hydraulic flow patterns created by the aerators. If these conditions become widespread, the aerobic uptake of phosphate might be less efficient. Indeed, in some instances no uptake was measured at all in plants which in every other respect should have supported phosphate removal. Phosphate removal in these circumstances took place in the secondary aeration stage, especially when the dissolved oxygen concentration was high. Experimentation has shown that even with submerged diffusion aerators, the dissolved oxygen concentration is limiting to successful phosphate uptake if maintained at approximately 1 mg/ℓ near the surface of the mixed liquor. Successful phosphate removal was measured with dissolved oxygen concentration controlled between 2 mg/ℓ and 3 mg/ℓ.

The Phoredox process is designed to provide a fully nitrified effluent and consequently depends on efficient denitrification to allow the implementation of the phosphate cycle. Due to the variable nature of the influent feed it is necessary to provide for changes in the primary anoxic retention time. Usually high nitrate concentrations in the effluent coincide with low feed COD concentrations. In these circumstances it should be possible to increase the anoxic retention time by switching off aerators at the head of the primary aeration stage. This action will correspondingly reduce the aerated retention time, but since the lower COD concentration requires less aeration time the effluent COD concentration will be unaffected. An undesirable result of this action might be the decline in nitrification efficiency if the process is left in this reduced aeration state too long.

A matter of great importance is the limiting of oxygen entrainment in the sludge recycle. Anaerobic conditions, in the anaerobic stage, can only develop after the nitrate concentration has been depleted. This denitrification will not take place until the available dissolved oxygen is utilized. The time required to reduce entrained oxygen and the recycled nitrate will increase with the increase in the concentration of either or both of these parameters. Therefore these concentrations must be limited in order to ensure successful phosphate release.

In a similar manner high dissolved oxygen concentration inputs to the primary anoxic stage will result in poorer nitrate reductions. Consequently oxygen uptake from atmosphere must be avoided in both the anaerobic and anoxic basins. Gentle stirring is necessary, since without it the mixed liquor solids will settle. Ideally the stirring provided should be sufficient to maintain a homogeneous mixed liquor without creating surface disturbances which cause oxygen entrainment. Some guidance on the power requirements necessary to provide sufficient scour is offered by Kalbskopf (1972).

OPERATIONAL CONSIDERATIONS

The biological process of phosphate removal is not an unnatural phenomenon, and if a nutrient removal plant is not functioning it is not the fault of the process. Every reactor is unique and in order to obtain the best results from it, it is necessary to have experienced operators who understand the theory of the process and the operational options available to them. In general, when the operational procedure has been developed for a given plant, it becomes a matter of routine to keep it running at its optimum efficiency. But there are times when operational adjustments become necessary and in order to allow the operator the best chance of making a correct decision instrumentation is essential. The instruments to be provided in addition to the usual electrical switching and power measurement boards, are flow measuring and recording devices as well as devices for dissolved oxygen concentration determination. Minimally, the influent feed flow should be measured, but if the two recycles are also metered it becomes very much easier to control the plant.

LIST OF SYMBOLS

Symbol	Description	Units
a	Mixed liquor recycle ratios	
COD	Chemical oxygen demand	mg COD/ℓ
MLSS	Mixed liquor suspended solids	mg/ℓ
MLVSS	Mixed liquor volatile suspended solids	mg/ℓ
$\triangle P$	Phosphate concentration removed	mg/ℓ
Q	Average influent flow	ℓ/d
R	Total nominal retention time of the reactor	hours
R_s	Sludge retention time for the reactor	days
$\triangle S$	Substrate concentration utilized	mg/ℓ
s	Sludge recycle ratio	
t	minimum temperature	°C
TKN	Total Kjeldahl nitrogen (as N)	mg/ℓ

One problem with the use of marshes in areas such as South Africa where the climate is suitable yearround for the growth of marsh plants is that evapotransporation from these marshes is enormous, and loss of water may be excessive for a country short of water.

WILE, et al. (?), BLACK (?), and HANNA (?) describe and discuss the effectiveness of marshland ecosystems in the removal of nutrients from sewage in an engineered system. Their work showed that during the ice-free period, phosphorus can be reduced to 0.2 mg/l in the marsh effluents. A 10-90% reduction in phosphorus levels were found due to the marshland treatment of sewage effluents. It was generally concluded that the results of large-scale tests were encouraging, but more work was needed to generate data suitable for use as engineering parameters.

INTRODUCTION

Selenium compounds are very toxic to a wide range of organisms including algae, some bacteria, aquatic microorganisms, and animals as well as land mammals and humans. Some of these, however, adapt to a selenium-rich environment. Selenium deficiency in animal diets is also very harmful.

Selenium enters the environment primarily through the weathering and erosion of rocks containing selenium-enriched mineralization. Other sources are in stackgases and ash from coal-fired power plants and in industrial effluents including those from some copper, lead, and zinc metal refining operations. Some coal spoils piles are also enriched in selenium.

Selenium is a particularly nasty element because of the way it concentrates in the food chain. One particular example is its concentration in certain plants that grow in selenium-enriched soils. Selenium in highly seleniferous plants can reach levels of 1,000

ug/g or more, and such plants are harvested for use as a food additive in selenium-deficient areas. Some aquatic bacteria also cause an accumulation of bottom sediments with enriched selenium levels which can prove toxic to fish.

Not all that much is known about selenium pathways into the environment nor about precisely what levels can be tolerated in water without damage. Analytical techniques and determination of the speciation of selenium also leaves much to be desired.

OCCURRENCE OF SELENIUM IN MINE-MILL ENVIRONMENTS

Selenium and selenium compounds are enriched in soids in large areas of the southwestern U.S.A. It also occurs with base sulfide metal ores and in coals.

Selenium occurs as selenide Se^{2-} in metal sulfide ores as discussed by HUTCHINSON (1959). When sulfide concentrates are roasted, selenium is oxidized to selenium dioxide which is released with SO_2 in the flue gases. When the flue gas is quenched and scrubbed, the SeO_2 reacts with the quench water to form selenious and H_2SeO_2. A selenium level of 0.7 mg/l has been reported in the wastewaters of copper smelting and electrolytic refining by HALLOWELL, et al. (1973). The selenite SeO_4^{2-} appears to be the most common from of selenium in wastewaters except for pigment and dye wastes which contain selenide (e.g., yellow cadmium selenide). Other forms decompose to yield the selenate SeO_4^{2-} ion.

Selenium may, therefore, be present in effluents from base metal refining operations and also in drainage from wasterock and mill tailings in these areas. Selenium may even be present in overburden and soils disturbed in the mining process. In base metal (Cu, Pb) smelting and refining, selenium in roaster and smelter gas quench and scrubber solutions will be much more concentrated than in the final effluent.

Selenium can also be present in rainwater, possibly introduced via coal-fired powerplants to the atmosphere. LYMBURNER and KNOLL (1973) reported analyses of coal, bottom, and flyash at 2 ppm, 3.4 ppm, and 41.3 ppm respectively, which are atypically high.

PATTERSON (1976) reported on the basis of limited data that industrial wastes often contain 1-10 mg/l selenium.

At a minewater settling pond at a New Mexico uranium mining complex, selenium was found by BRIERLEY, et al. (1980) to be removed from water to some extent. Bacterial and algal populations present in the pond system are considered to actively help remove selenium along with some other contaminants as discussed below.

Disposal of effluents and precipitate sludges containing selenium may, in fact, create new sources for future contamination.

OCCURRENCE OF SELENIUM IN NATURE

Selenium occurs in the earth's crust quite commonly at an average level of 7×10^{-5} percent. It is usually present as heavy metal selenides (together with sulfide minerals), but it also occurs as selenates and selenites. In soils around the Great Lakes region, selenium is present at levels ranging from 0.1 ug/g to less than 2 ug/g according to COOPER, et al. (1974). Elevated levels of selenium formations and their derived soils occur in central Canada and the U.S.A., particularly in the desert southwestern U.S.A.

There are no known mining activities for selenium, and its production comes mostly as a by-product of copper and lead refining.

Commercial use of selenium was about 500 tpa in 1968, mostly in the elemental form as red crystals or grey powder. It is used in electronics for rectifiers, photocells, and xerography. It is also used in steel and in pigments for paints, glass, and ceramics according to COOPER (1967) and LYMBURNER and KNOLL (1973).

Selenium is usually present in water as selenate and selenite; the elemental form is insoluble but may be carried in suspension. The weathering of rocks and soil erosion are major sources of selenium in water. An estimated 10,000 metric tons of selenium are annually weathered and carried downstream to the sea. Of this, an estimated 140 tons is in solution, but only 16 tons remains dissolved in the sea--the rest ends up in sediments according to SCHROEDER (1974).

Sewage in California (both raw and treated) was found to have only 10-60 ppb selenium except for a high value of 280 ug/l in an industrial area as reported by FELDMAN (1974).

The increasing interest in the use of incineration for garbage disposal in large municipal sanitary disposal operations near major metropolitan areas leads to some concern about selenium release as an air pollutant on incineration of paper products. For incinerator fly ash quench, water soluble selenium was measured at 5-23 ug/l while incinerator residue quench water contained 3 ug/l soluble selenium at an incinerator which handled a solid waste containing 55-70% paper according to JOHNSON (1970).

Concentrations of selenium in water are usually low. Several literature reviews are available including one by NAS/NAE (1973), but most older estimates of selenium are probably too high because of the limitations of older chemical analytical methods. However, some wells probably exceed the drinking water standard of 10 ppb in the U.S.A. and 50 ppb in Ontario.

According to ONTARIO (1979), most uncontaminated surface waters contain less than 50 ug/l Se, and most drinking waters contain less than 10 ug/l (APHA, et al., 1971).

Surface waters in a part of Germany averaged 4 ug/l according to HEIDE and SCHUBERT (1970).

In seawater, the normal concentration of selenium is only 0.4 ug/l (CHAU and RILEY, 1975). Even seepages from seleniferous areas do not contain more than 500 ug/l, and this content is lost when the seepages discharge into ponds or lakes, apparently by coprecipitation with ferric hydroxide (APHA, et al., 1971).

Selenium concentrations in the Great Lakes are below 1 ug/l offshore, and mean concentrations are 0.2 ug/l or less.

Lake sediments seem to act as sinks for selenium; in the northern U.S.A., they contain 1.0-3.5 ug/g dry weight of selenium, considerably more than the usual concentration in soils (WIERSMA and LEE, 1971). Small ecosystem experiments showed that of the total amount of selenium in rain which fell on soil, 75% stayed in the soil, and 25% ran off into an aquatic system. 36% of the selenium that entered the aquatic system ended in the sediments, and most of the remainder was in the biota according to HUCKABEE and BLAYLOCK, 1974.

Deficiency of selenium in soil and in grass eaten by livestock leads to "white muscle disease." The dietary needs of livestock are in the range of 0.1-0.2 mg/d according to NAS/NAE (1973). The daily needs of selenium in the human diet is not precisely known and appears to be in the range of 0.1-0.2 mg/d according to LEVANDER (1975). Adequate diets normally contain that much selenium according to NAS/NAE (1973).

Selenium is highly toxic to animals, but poisoning generally results from eating selenium-concentrating plants. A concentration in water of 0.4-0.5 mg/l was reported by

McKEE and WOLF (1963) to be non-toxic to cattle. HEM (1970) commented that water with selenium concentrations higher than 0.5 mg/l but satisfactory in other respects for livestock watering may exist, but that it would be unusual. Toxic substances of other kinds may be present in polluted water, and incidents of poisoning of animals by drinking polluted water in the U.S.A. are not unusual.

In the 1930's it was discovered that a disease of livestock in parts of the western U.S.A. was caused by an excessive intake of selenium. The agricultural significance of selenium has been summarized by ANDERSON, et al. (1961).

Some plant species of the genus Astralagus are particularly notable for their selective concentrating ability of selenium from the soil, and some plants have been found with several thousand mg Se per Kg dry weight.

Usually, water draining from seleniferous soils--which may contain up to 1 mg/l Se--also contains such high TDS that it is rendered unsuitable for drinking water by other constraints.

Selenium poisoning of livestock is divided into two classes: The acute type called "blind staggers;" and the chronic type called "alkali disease."

The accute type is caused by ingestion of highly seleniferous plants containing 1,000 ug/g or more of selenium, whereas chronic selenium toxicity is associated with grains and plants containing 5-20 ug/g selenium according to MOXON (1958). There is extensive literature on livestock poisoning due to selenium in food plants which indicates that 5 ug/g or more can lead to death in a herbivore, and that such levels can result in plants from soil concentrations of 0.5-6 ug/g according to ONTARIO (1979). A diet containing only 3 ug/g selenium in selenite form killed rats according to SCHROEDER (1967).

ONTARIO (1979) reviews numerous examples of selenium toxicity tests to fish in which levels of 2-20 ug/l were toxic in various degrees to a variety of fish. Concentrations of selenium in fish tissue in Canada ranged from 0.16-0.6 ug/g wet weight which is a comparable level to Se in fish tissue in New York and Finnish water. In the Great Lakes, however, Se concentrations in fish from the North Channel of Lake Huron, Georgian Bay, Lake Erie, and Lake Ontario ranged at 0.56-2.0; 0.42-1.14; 0.10-0.75; and 0.06-0.96 ug/g respectively.

BARNHART (1958) reported fish mortality in a Colorado reservoir as being caused by selenium from bottom deposits which has passed through the food chain to accumulated levels of 300 ug/g in an isolated case.

Fish absorb selenium principally from food and show little uptake from inorganic or organic selenium forms in water. Some species of aquatic invertebrates take up organic selenium while others seem to be able to take up selenium from inorganic forms too.

The livers of some seals contain 46-134 ug/g selenium according to KOEMAN, et al. (1973) which is much higher than the 0.5-1.3 ug/l level found in the livers of land animals. Tissue from a northern Canadian beluga whale contained 14.3 ug/g selenium.

Because the difference between optimal and toxic intake levels in the food is comparatively narrow, 25-40 times according to HOFFMAN, et al. (1973), the possibility exists that fish-eating birds and mammals may be subject to a dangerous accumulation of selenium.

ONTARIO (1979) recommended more stringent limits for selenium in drinking water than for aquatic biota.

Selenium is biologically methylated and CHAU, et al. (1976) demonstrated methylation of sodium selenite, soldium selenate, selenocystine, selenourea, and seleno-DL-methionine by microbial action in lake sediments. All sediments which demonstrated microbial action were capable of methylating selenite and/or selenate. Mono and dimethylselenide were produced.

RODEN (1982) reported what may be a useful technique for the determination of inorganic selenium species in groundwaters containing organic interferences by ion chromatography and hydride generation/atomic adsorption spectrometry.

REGULATORY LIMITS FOR SELENIUM

The 100 ug/l Se level considered safe to protect the aquatic environment by ONTARIO (1979) may be too high if bioaccumulation effects are to be taken into account.

The U.S. EPA (1980) freshwater criteria is 35 ug/l total recoverable inorganic selenite as a 24-hour mean concentration. Maximum permissible concentration of total recoverable inorganic selenite is 260 ug/l.

ENVIRONMENT CANADA (1979, 1979a) set a freshwater criteria of 10 ug/l total Se.

The U.S. EPA (1980) marine criteria for total recoverable inorganic selenite as as 24-hour mean concentration is 54 ug/l with 410 ug/l as total recoverable inorganic selenite maximum permissible concentration.

Industry observers concluded that the above objectives for Se in fresh water may be on the lenient side if bioaccumulation effects are to be taken into account.

There is not enough information about the toxicity of selenium in the marine environment to be able to establish a reliable objective and/or criterion.

The maximum permissible limit for selenium according to the U.S. EPA (1980) is 260 ug/l with a 24-hour mean maximum of 35 ug/l.

None of the operating mine-mill discharge permits encountered in the course of this investigation included a specific limit for selenium. However, several NPDES permits, including that for the HOMESTAKE MINING COMPANY's McLaughlin project in California would cover selenium in the following catch-all paragraph:

Se (ug/L) SELENIUM

Summary of North American Water Quality Criteria for Selenium

"5. The discharge shall not cause sedimentation or concentrations of any materials in the receiving waters which are deleterious to human, animal, aquatic, or plant life." CRWQCB (1983)

On August 27, 1971, the New Mexico Water Quality Control Commission enacted a state-wide regulation that effluents of any sort in New Mexico must contain less than 0.01 mg/l total selenium.

The South African Bureau of Standards' Revision 241 of 1971 sets a recommended and maximum allowable limit for selenium in any public water supply of 0.02 and 0.05 mg/l selenium. The South African Government Notice R553 of 1983 proposed a new standard for effluents which would not be permitted to contain more than 0.05 mg/l Se.

Although Se is not specifically mentioned in most effluent discharge permits, RANDOL INTERNATIONAL LTD. believes that in the event of Se contamination of groundwater and/or surface water by an operation in most industry centers to the extent of environmental damage or impairment of the use of the water, litigation would result against the owners of the cause of the contamination. In the U.S.A. there is little question about this given the present status of CERCLA and state regulations.

The public water supply limit for selenium in the U.S.A. is 10 ug/l which is the same as in Ontario; however, the federal Canadian limit is 50 ug/l Se.

PATTERSON (1979) listed the following industries as major industrial sources of metal containing wastewaters: paint, pigment and dye production, electronics and glass manufacturing, pulp and paper production, and nonferrous metals smelting.

Selenium was listed as a regulated metal for direct dischargers under BPCTCA, BATEA, or NSPS by the following industries:

Inorganic Chemicals
Nonferrous Metals

These are the only two of a host of industry catagories. The regulations governing nonferrous metal smelting were not encountered during this investigation.

PATTERSON (1979) listed a range of concentration limits for metals in effluent limitations under BPCTCA, BATEA, and NSPS.

	Average (30-Day mg/l)	Maximum (24-Hour mg/l
Se	0.5-5.0	1.6-10.0

The Illinois Effluent Standards Advisory Group, as part of the Illinois Institute for Environmental Quality, published an "Evaluation of Effluent Regulations in the State of Illinois" in which they recommended achievable effluent limits for a variety of metals. For selenium, no conventional control technology was recommended nor was an achievable limit reported.

TREATMENT FOR SELENIUM REMOVAL

Selenium may occur as selenium metal, selenides, selenite, and selenate. Its chemistry in this respect is somewhat analagous to sulfur.

SO_2 REDUCTION AT ACID pH

One difference between selenium and sulfur is that selenium compounds or ions can be removed by the addition of SO_2 and by the addition of soluble sulfide ions in some cases. The mechanisms for this were not found during this investigation. However, it was indicated by John Shafer of EXXON Production Research that selenite is easily reduced to selenium metal by SO_2 at an acid pH. However, reduction of selenate requires the presence of high concentrations of chloride ions. Even where equilibrium diagrams indicate that selenate should be reduced, the kinetics can be very slow.

The logical method to be selected for selenium removal from solutions or effluents would depend on the nature and volume of the solution to be treated, the end-use destination of the treated solution, i.e., recycle or discharge as effluent, and the concentration of selenium in the solution to be treated.

Considering the low levels of selenium that must be achieved in an effluent to meet an environmental protection objective of 10 ug/l (the U.S.A. is currently 100 ug/l but subject to change), it would seem logical to find the main source of selenium in the operaton and to isolate a smaller flow of more concentrated solution for treatment rather than trying to treat the total plant effluent which would have a much larger volume and a lower, more difficult to treat concentration of Se.

Methods for Se and Se compound/ion removal include:

Chemical and amortization costs for a weak-base ion exchange system. [From Ahlgren (9), courtesy of *Industrial Water Engineering*.]

1) SO_2 Treatment
2) Settling
3) Lime Precipitation
4) Coagulation/Settling Using Fe Salts
5) Sulfide Treatment
6) Biological
7) Ion Exchange

It has been reported (PATTERSON, 1975) that selenium dioxide is readily reduced, which precipitates, finely-divided elementary selenium. He indicates that it is probable that the same reaction might occur for selenious acid H_2SeO_3 at acidic pH. In fact, a selenium by-product is believed to be recovered by sparging SO_2 into acidic roaster/smelter fluegas scrubber water at a base metal smelter-refinery in El Paso, Texas (NEWMONT or ASARCO?) Adsorption of slenite and selenate clearly plays an important role in its removal from solution which also appears to be pH dependent.

Selenide may be precipitated as the metal salt which, according to HUTCHINSON (1979) is also very sparingly soluble.

ACTIVATED CARBON

Secondary municipal sewage treatment plant effluents containing 2-9 ug/l selenium have been reported by ARGO and CULP (1972). Tertiary treatment by a sequence of lime addition to pH 11, sedimentation, mixed media filtration, activated carbon, and chlorination yielded selenium removal of 0% up to 89%. Best selenium removal was obtained at higher selenium concentrations. Activated carbon treatment of secondary treated municipal wastewater reduced selenium from 9.32 to 5.85 ug/l or a 37% reduction in a case cited by CULP and CULP (1974). LOGSDEN, et al. (1974) reported less than 4% removal of selenite ions from well water. This suggests that species in the treated municipal sewage may have been formed which are more easily removed by activated carbon than selenite ions. Possibly, organo-selenium compounds or chelated selenium compounds are present in the sewage.

LOGSDEN, et al. (1974) reported pilot plant test results.

ANION EXCHANGE

LINSTEDT, et al. (1971) concluded that selenium removal from effluents could be achieved with a strong acid-weak base ion exchange system. The capital and operating costs of such dual-bed ion exchange systems is strongly dependent on the dissolved solids content

as shown in the curves below. Although their actual costs per 1,000 gal. will be out of date, the relative influence of dissolved solids on cost will have remained unchanged.

REMOVAL OF SELENIUM BY BENCH SCALE ADVANCED WASTEWATER TREATMENT PROCESSES: LINSTEDT, ET AL. (1971)

Original Se Concentration: 2.3 ug/l.

Process Tested	Percent Removal
Lime Coagulation - Settling	16.2
Cation Exchange	0.9
Cation plus Anion Exchange	99.7
Process Sequence (Cumulative Removal)	
- Step 1 - Sand Filtration	9.5
- Step 2 - Activated Carbon	43.2
- Step 3 - Cation Exchange	44.7
- Step 4 - Anion Exchange	99.9

LINSTEDT, et al. (1971) did not report the efficiency of straight anion exchange without the other pretreatment steps. It must also be remembered that these results relate to the treatment of secondary sewage effluent which may have completely different removal properties compared with metallurgical effluents which have not been in contact with organics which demonstrated that neither ferric sulfate nor alum coagulation are very effective and that removal efficiency improves with increasing coagulant dosages and decreasing pH.

PILOT PLANT SELENITE REMOVAL BY COAGULATION

Initial Concentration: 0.09-0.10 mg/l Se as Selenite.

	pH	% Removal
Ferric Sulfate Coagulation		
- 25 mg/l	7.0	60
	5.5	78
- 60 mg/l	7.0	75
	5.5	83
- 100 mg/l	7.0	81
	6.0	84

		SELENIUM
Alum Coagulation		
- 25 mg/l	6.0	10
- 100 mg/l	6.0	27
- 200 mg/l	6.0	45

LINSTEDT, et al. (1971) measured 2.3 ug/l selenium in the effluent from a secondary sewage treatment plant. These workers investigated the efficiencies of removal of selenium as SeO_3^{-2} by several advanced wastewater treatment processes. His results were shown on the previous page as reported by PATTERSON (1975).

LIME PRECIPITATION

A major mineral company recently tested selenium precipitation with lime on a pilot scale. Reputedly, selenium was effectively precipitated, and the sludge could be settled efficiently. The settled sludge, when fresh, also passed the EP leach test. However, after standing for some months, the EP leach test could no longer be met as selenium became soluble as the precipitate aged. This phenomenon is possibly due to conversion to the carbonate due to action with CO_2 in the atmosphere or the resulting reduction in pH. Although selenium and selenium anions do not form carbonates, possibly calcium selenites are converted to calcium carbonate and free selenite ions in an analagous way to arsenate resolubilization from lime precipitate sludges as described by ROBINS in the section on arsenic. Certainly pH effects on resolubilization of selenium have been noted.

SULFIDE ADDITION

At a North American base metal processing facility which prefers not to be identified, selenium occurs in a sulfuric acid waste stream with a volume of 50-75 U.S. gpm. When this stream is neutralized with lime, gypsum precipitates and settles and carries the selenium with it. However, the gypsum sludge does not pass the EP leach test and would be classed as a hazardous waste. The answer is to precipitate selenium first by the addition of NaHS or H_2S and thereafter to neutralize the acid stream. In this way, the precipitated and settled sludge passes the EP leach test. It is not known whether the sludge is stable when in contact for months with water in equilibrium with atmospheric CO_2, nor in what form the selenium is removed by sulfide addition. Adsorption?

BHATTACHARYYA (1979) reported that precipitation with Na_2S is a highly effective method to obtain a high degree of separation of metal cations such as Cd, Zn, Cu, and Pb, and of the oxyanions of arsenic and selenium from complex wastewaters. The metal separation characteristics are evaluated with a dilute synthetic mixture and with an actual copper smelting plant wastewater. The overall separation of arsenic and other heavy metals and precipitate settling rates were found to be optimal at sulfide dosages about 60%

of the theoretical values and at a final pH greater than 8.0. The removal of Cd, Zn, and Cu from the actual wastewaters are greater than 99% and As and Se removals are 98 and more than 92% respectively. These data are of interest because they indicate that sulfide addition is somewhat less effective for Se removal than for most other base metals, although this may be due to the much lower levels of Se in solution.

WILMOTH, et al. (1979) tested lime neutralization, reverse osmosis, and ion exchange for their effectiveness in removing various trace elements including selenium from acid mine drainage. They found that all three processes removed Se as well as As, Cd, Cu, Hg, Ni, and Zn from acid mine drainage but not B and P. R.O. and IX were slightly more effective overall than neutralization, but the chemical requirements and need for subsequent waste treatment to handle and dispose of the concentrates offset their advantages.

Jim W. Kauffman of KERR-McGEE's technical center in Oklahoma City was quoted in C&EN, September, 1984, page 45, as saying that the selenium levels were then too high in minewater from Ambrosia Lake, New Mexico, uranium mines to be environmentally acceptable. However, preliminary laboratory and field tests showed dynamic removals of contaminants including selenium by soil-supported bacteria. The effectiveness of the process was found to be influenced by temperature, flow rate, and the presence or absence of cometabolite nutrients such as sucrose, lignosulfonate, and refining sludges. KAUFFMAN (1984) indicated the belief that the bacteria reduce minewater selenate to insoluble red amorphous selenium metal which is retained in the cell.

BRIERLEY, et al. (1980) and BRIERLEY and BRIERLEY (1981) reviewed contamination of ground and surface waters due to uranium mining and milling at the Ambrosia Lake district of New Mexico. This wastewater contains uranium, selenium, radium, and molybdenum. The KERR-McGEE CORPORATION has a novel treatment process for water from their mines 35 and 36 to reduce the concentrations of the trace contaminants. Particulates are settled by ponding, and the waters are passed through an ion exchange resin system to remove uranium. Barium chloride is added to precipitate radium as barium radium sulfate. The mine waters are subsequently passed through three consecutive algae ponds prior to discharge. Water, sediment, and biological samples were collected over a four-year period and analyzed to assess the role of biological agents in the removal of inorganic trace contaminants from the mine waters.

BRIERLEY, et al. (1980) refer to bacterial and algal populations present in the pond system which are considered agents which actively assist in the removal of the pollutants in the water. Pond-bottom sediments maintain a reducing zone and a large population of sulfate-reducing bacteria of the genera Desulfovibria and Desulfotomaculum. Uranium, molybdenum, and selenium accumulate in the pond sediment. Stimulation of the microbial sulfate-reducing activity resulted in a decrease of soluble concentrations of these elements in laboratory systems. Predominant components of the treatment ponds' algal flora are

the filamentous Spirogyra and benthic Chara. Laboratory study indicates that spirogrya is more active than Chara in the removal of uranium and molybdenum from solution, but their paper does not mention the effects of the algae on selenium removal. Nonetheless, sulfate-reducing bacteria at the pond bottom are likely to generate sulfide ions which are known to remove selenium from solution although the mechanism for this is not yet clearly understood.

SELENIUM

The Chemistry of Selenium in Water

Selenium has five valence states: -2, 0, +2, +4, and +6. Only the +2 state has not been reported in nature. The higher valent oxides of selenium are powerful oxidizing agents, having a redox potential close to that of water: Se(VI/IV) 1.15 V; O_2/H_2O 1.23 V. The +6 oxide of selenium, selenate, is stable under acid and alkaline conditions. At alkaline pH values selenate is very soluble (Cotton and Wilkinson, 1972; Downes et al., 1979; National Research Council, 1976). Selenite, the +3 oxidation state, is much less soluble than selenate and is only weakly acid. At pH values from 3.5 to 9 biselenite ion would be the expected ion. Selenite is readily reduced to elemental selenium under acid conditions by mild reducing agents. In nature selenite is usually rendered insoluble by reduction to elemental selenium or formation of insoluble selenide compounds (National Research Council, 1976). Elemental selenium is extremely insoluble and can be considered a "sink" for selenium in the environment. The -2 oxidation state, selenide, occurs as inert, metal selenides. These are also considered "sinks" for selenium in the environment. There is some evidence, however, that metallic selenides may be oxidized to selenates by microbes (Downes et al., 1979; National Research Council, 1976).

The selenium content of surface waters is a function of the water's ionic content, pH (Lakin, 1973) and Eh (National Research Council, 1976). At pH 6.3-6.7 selenium is precipitated as basic ferric selenite (Howard, 1971; Lakin, 1973; Measures and Burton, 1978; Trudinger et al., 1979). In natural waters ferric hydroxide adsorbs one to two orders of magnitude more selenite per weight than kaolinite or montmorillonite; adsorption of selenium by humate is negligible. Removal of selenite by iron hydroxides concentrates selenium in sediments where the action of sulfate-reducing bacteria convert the material to a seleniferrous pyrite (Howard, 1971). If the pH of the aqueous system is about 8, selenite may be oxidized to soluble selenate (Lankin, 1979; Measures and Burton, 1978). Organic selenium species are not likely to be present in natural waters since these species would probably be hydrolyzed into selenide and then oxidized biologically (Robberecht and Van Grieken, 1980).

The Chemistry of Selenium in Biological Systems

The organic chemistry of selenium and sulfur is quite similar. Selenium may be concentrated in organic matter by substituting for sulfur in sulfur-containing amino acids (Lakin, 1973) to form selenocysteine and selenomethionine. Selenium in biological systems is usually as a selenol, RSe-H, or as a selenium ether, R_2Se. Because the selenols will be anionic in biological matter, they make good nucleophiles and good leaving groups. Consequently, selenium in these systems has an advantage over sulfur because it is more reactive. RSe^- is a strong binding agent of heavy metals

(William, 1978). In addition to being incorporated into amino acids, selenium can be methylated by biological systems to form dimethyl selenide ($(CH_3)_2Se$) and dimethyl disenlenide ($(CH_3)_2Se_2$) (Dence, 1973). The volatile organo selenium compounds are characterized by their unpleasant and strong, garlic-like odor (Downes et al., 1979).

Selenium Accumulation by Microorganisms

Groups of microorganisms, including bacteria, actinomycetes and fungi were examined for their ability to accumulate selenium. All of the groups accumulated from 0.03 to 0.18% selenium on a dry weight basis. The concentration in the cells exceeded that of the medium by factors of 60-430. Accumulation was proportional to the selenium content of the medium (Koval'skiy et al, 1968). During a study of trace element contamination of a drainage from a coal basin it was observed that bacteria had accumulated the greatest amount of selenium of all of the organisms examined from the different trophic levels of the drainage system (Guthrie and Cherry, 1979). Fungi have been noted to accumulate large concentrations of selenium. The yeast, Saccharomyces uvarum, was able to accumulate selenium from a medium containing 10 ppm SeO_2. Dried cell preparations contained 2000 ppm selenium (Yamada et al., 1978; Yamada et al., 1979). Filamentous fungi were found to accumulate selenium most rapidly during the period of intensive mycelial growth. The transport of selenate through the mycelia of the filamentous fungi, Penicillium and Aspergillus, occurs via a permease enzyme which is common for the anions, sulfate, thiosulfate, selenate, and molybdate. This permease is energy-, temperature-, pH-, and concentration-dependent (Tweedie and Segel, 1970; Downes et al., 1979; Stadtman, 1974; Stadtman, 1977).

In organisms which perform "assimilatory sulfate reduction", i.e. organisms which reduce small amounts of sulfate for sulfur-containing cellular components, selenium probably follows the same path as sulfate. Selenate can react with ATP to form 5'-adenosine phosphoselenate (APSe):

$$SeO_4^{2-} + ATP \rightleftarrows APSe + \text{pyrophosphate}$$

This reaction is catalyzed by the enzyme adenosine triphosphate-sulfurylase. APSe is less stable than APS, probably because the enzyme-bound APSe has more of a tendency to transfer the selenate to the enzyme or to water. The APSe is thought to form 3'-phosphoadenosine-5'-phosphoselenate as follows:

$$APSe + ATP \rightleftarrows PAPSe + ADP$$

PAPSe would be the presursor of selenite. This reaction has only been demonstrated indirectly, and it is not known whether APS kinase, the enzyme that catalyzes the formation of PAPS from APS, can react with APSe to form PAPSe. The six electron reduction of sulfite to sulfide is catalyzed by the enzyme sulfite reductase. This enzyme has been highly purified from some microbes, and analyses have shown the enzyme to have many components. Sulfite reductase is relatively non-specific in terms of its electron

acceptor and will reduce hydroxylamine and sometimes nitrite. Although it has never been specifically examined, sulfite reductase may reduce selenite. Once sulfide is formed it is introduced into the synthetic pathway by the enzyme cysteine synthase. If this enzyme can use selenide, this would be the mechanism for the formation of selenocysteine (Stadtman, 1974).

It has not been demonstrated whether organisms such as Desulfovibrio, which perform "dissimilatory sulfate reduction", i.e. sulfate reduction which is associated with the energy metabolism of the organism and is quantitatively significant, will use selenate as an electron acceptor. If such a reaction does occur it would involve the enzyme APS reductase which would reduce selenate to selenite (Stadtman, 1974).

Toxicity of Selenium to Microorganisms

The toxicity mechanism of selenite differs from that of selenate. The toxicity of selenite may be directly related to the reactivity of the ion since selenite is a strong oxidizing agent (Tilton et al., 1967). Selenite is thought to inhibit growth by the oxidation of sulfhydryl enzymes (Prakash et al., 1972). Through this action, selenite is reduced to elemental selenium (Kumer and Prakash, 1971). Selenite may also become incorporated between two sulfur atoms in an enzyme to form intramolecular selenotrisulfide bridges. This renders the enzyme inactive by disrupting the native structure of the enzyme (Diplock, 1976). The toxic action of selenite probably differs from that of other selenium compounds, but these mechanisms have not been clearly elucidated (Kumar and Prakash, 1971; Silverberg et al., 1976). The toxicity of selenate may result from the competitive inhibition of sulfate transport by selenate. Selenate may also be toxic because of the instability of adenosine 5'-phosphoselenate (Tweedie and Segel, 1970) and other selenium-containing species such as selenoproteins and 4-seleno-uracil in tRNA (Downes et al., 1979). In the green alga, Chlorella, selenate and selenomethionine block the metabolic uptake of methionine and the production of methionine, respectively (Shrift, 1954; Shrift, 1958).

Selenate at a concentration of 100 μg $m\ell^{-1}$ was found to be inhibitory to the growth of the fungus, Penicillium sp., but this inhibition could be reversed by the addition of sulfate. At 0.1 M sulfate the fungus grew in the presence of 1000 μg selenate per $m\ell^{-1}$. It is thought that sulfate competitively inhibits selenium entrance to the cell (Tilton et al., 1967; Kumar and Prakash, 1971). It is not known whether this protection occurs at a metabolic level or whether adsorption of selenium is affected.

The Adaptation of Microorganisms to Selenium

Organisms isolated from seleniferous soils were found to be more resistant to selenium than microorganisms isolated from soils having low selenium content (Koval'skii et al., 1968a). However, even microbes isolated from soils with little selenium adapted to

the element when placed in media containing higher concentrations of the element (Koval'skii et al., 1971).

Microbes in general are adaptable to metal concentrations, however, metal speciation is a factor in microbe adaptation. Some selenium species can be more toxic than other species. The blue-green algae, Anacystis nidulans and Anabena variabilis, exhibit a definite lag-time when cultured in sub-lethal concentrations (<200 ppm) of selenate, selenite, selenomethionine and selenopurine (Kumar and Prakash, 1971). However, both blue-green algae genera are more tolerant to selenate than selenite. Selenium, as 10 ppm of aqueous solution of SeO_2, was found to inhibit oxygen consumption by organisms in a soil/litter microcosm. The effect was immediate; however, a delay in inhibition of several hundred hours was noted if both aqueous SeO_2 and $CdCl_2$ were applied to the microcosm. This delay was not explained (Lighthart and Bond, 1976), but could be attributed to the protective effects that some heavy metals demonstrate (Allaway, 1975; Downes et al., 1979; Ganther et al., 1972; Oldfield, 1972; William, 1978; Wood et al., 1975). Selenite was found to inhibit nitrification in some soils. In these experiments 3 mℓ of a 50 μmole solution of H_2SeO_3 was applied to 10 g of soil. It was found that chemical and physical properties of soils as well as the nature of the nitrogen in the soil affected the inhibition of nitrification by selenium and other trace elements. Selenite has little effect on nitrification in calcareous soils (Liang and Tabatagai, 1977). Studies with diatoms showed that these organisms grew well at selenite concentrations of 1, 10, 40 mg ℓ^{-1}, but the diversity of the species was reduced at the highest concentration tested (Patrick, 1978). In another experiment selenate concentrations from 1-10 mg ℓ^{-1} were all toxic to diatoms; however, the blue-green alga, Schizothrix calcicola, was common even at the highest selenate concentration. There is one report that microbial nitrogen fixation and carbon consumption were enhanced by 25-100 μM selenium as SeO_2 (Jaiswal and Bahadur, 1974).

The Oxidation and Reduction of Selenium by Microorganisms

Reduction:

The reduction of selenite to elemental selenium by microorganisms is well documented. Whether this reaction is catalyzed by a specific enzyme is not positively known (Summers and Silver, 1978), although an induced adaptive enzyme, conditionally termed selenium reductase, has been proposed through studies with Bacillus megaterium (Koval'skii et al., 1968b). Reduction of selenite by Bacillus megaterium occurred at selenite concentrations of 10-100 μg mℓ$^{-1}$ and a pH of 6.4. Divalent cations, such as calcium, magnesium, manganese and cobalt, at low concentrations (0.2-6.0 mg mℓ$^{-1}$) acted as activators of selenite reduction but at higher concentrations these cations were inhibitory to the reductive process. The role of these cations is not known (Koval'skii et al., 1968a).

Work with Candida albicans also indicated that selenite

reduction to elemental selenium is an enzymatic process. Enzymatic activity disappeared upon dialysis. The coenzyme source included a quinone, a thiol compound, a pyridine nucleotide, and an electron donor (Koval'skii et al., 1968a).

The reduction selenite has been used as a differential test for the separation of members of the enterococcus group of bacteria, but the physiological implications of this capacity for selenite reduction have not been elucidated (Tilton et al., 1967). It is known that the growth of the organisms is not coupled to selenite reduction (Tilton et al., 1967).

Escherichia coli also reduces selenite to elemental selenium. When this occurs the broth cultures turn brick red. Observation of electron micrographs revealed that the elemental selenium was deposited on the cell membrane and cell wall rather than in the cytoplasm of the organisms (Gerrard et al., 1974). In other studies, using the transmission electron microscope and energy dispersive x-ray analyses, opposite results were obtained. Elemental selenium formed by the reduction of selenite by Pseudomonas sp. and Escherichia coli appeared as electron dense inclusions in the cytoplasm, and no deposits were observed in the cell wall (Silverberg et al., 1976). The selenium inclusions were distributed randomly throughout the cytoplasm. When elemental selenium inclusions were observed in Aeromonas and Flavobacterium, large fibrillar formations and spherical granular deposits were seen (Silverberg et al., 1976).

Oxidation:

Elemental selenium has been reported to be oxidized to selenate by soil microorganisms. Micrococcus selenicus reportedly oxidized selenide to selenate (Ehrlich, 1978). Both of these reactions are energetically favorable for microbial growth:

$$Se^{\circ} + H_2O + {}^{3}/_{2}O_2 = H_2SeO_4 \qquad \Delta G^{\circ} = -67.83 \text{ kcal}$$

$$Se^{2-} + O_2 = SeO_4^{2-} \qquad \Delta G^{\circ} = -142.62 \text{ kcal}$$

Thiobacillus ferrooxidans has been shown to oxidize copper selenide to cupric ion and elemental selenium (Sakaguchi et al., 1978):

$$CuSe + {}^{1}/_{2}O_2 + 2H^{+} + Cu^{2+} + Se^{\circ} + H_2O \qquad \Delta G^{\circ} = -33.26 \text{ kcal}$$

CuSe is an insoluble material, so oxidation of the selenide must occur by a mechanism similar to that used by T. thiooxidans for the oxidation of sulfur (Ehrlich, 1978).

Methylation of Selenium by Microbes

Methylation Processes:

Biological methylation was first reported by Challenger in 1945 (Challenger, 1945). He noted that, through the action of molds, organometals and organometalloids could be formed. It was proposed that methylation processes were a mechanism that organisms

used for detoxification of their environment (Lakin, 1972).

Methylation of selenium is carried out by a number of organisms including fungi, bacteria and higher plants and animals (Lakin, 1972). Methylated selenium compounds are volatilized from soil, and this activity is attributed to microbial methylation processes (Abu-Erreish et al., 1968; Barkes and Fleming, 1974; Doran and Alexander, 1976; Doran and Alexander, 1977; Francis et al., 1974; Hamdy and Gissel-Nielsen, 1977; Lakin, 1972).

Gases produced through methylation of selenium include dimethylselenide, $(CH_3)_2Se$, dimethyl diselenide, $(CH_3)_2Se_2$ and other unidentified volatile compounds. Like other methylated metals, organoselenium compounds are more toxic and have longer retention times than inorganic selenium salts (Lakin, 1972; Wong et al., 1975).

The production of methylated selenium compounds results from the alkylation of selenite or selenate (Barkes and Fleming, 1974; Wong et al., 1975), elemental selenium, selenomethionine, selenocystine, and methaneseleniate (Doran and Alexander, 1977). In studies using Corynebacterium S- adenosylmethionine was used as a cofactor to transfer methyl groups to the selenium (Doran and Alexander, 1977). From this study there was evidence that the organism first reduced inorganic selenium before methylation. Both stereoisomers, D- and L- methionine will serve equally as well as methyl donors for the methylation of selenium (Dransfield and Challenger, 1955).

Challenger has proposed a mechanism for the biological methylation of selenate (Challenger, 1978). This mechanism is outlined below:

$$SeO_2(OH)_2 \rightarrow CH_3SeO(OH) \rightarrow (CH_3)_2SeO_2 \rightarrow (CH_3)_2SeO \rightarrow (CH_3)_2Se$$

The scheme involves ionization, reduction and the coordination of a positive methyl group. L- and D-methionine is believed to be the methyl donor for reactions occurring in microorganisms (Challenger, 1978).

The formation of dimethyldisulfide has also been proposed to be analogous to the production of dimethyl sulfide from methionine. In this case methane thiol is cleaved from the amino acid, methionine, and the methane thiol is oxidized to dimethyl sulfide (Doran and Alexander, 1977).

Selenium Methylation in Water:

Methylation of selenium occurs not only in soil but in aquatic environments as well (Chau et al., 1976; Thompson, 1977).

Dimethylselenide was generated from raw sewage, and this was thought to be the result of the activity of the fungus, Penicillium (Fleming and Alexander, 1972).

Sediments enriched with selenite, selenate, selenourea, and seleno-DL-methionine produced dimethyl selenide and dimethyldiselenide. Pure cultures of organisms, believed to be species of Aeromonas, Flavobacterium and Pseudomonas, isolated from the sediments, were responsible for the methylation. The methylation process was observed to occur under both aerobic and anaerobic conditions (Chau et al., 1976).

CHAPTER 49

SILICA SiO_2

Silica is present in almost all minerals and occurs in fresh water in a range of 1-100 mg/l according to NALCO (1979). Surface waters are often affected by seasonal diatom blooms, and diatom skeletons consist of pure silica. Silica behaves like a colloid in its reaction with adsorbents like MgO and $Fe(OH)_3$. At high concentrations, over 50 mg/l, the adsorption isotherms no longer apply, and silica behaves as a chemical precipitate. KEMMER (1979) postulates that there is probably an equilibrium between silica in colloid form and the bisilicate ion $HSiO_3^-$. In acid metallurgical solutions, silica may be in the form of H_2SiO_3. Because of this complexity, it is difficult to predict the conditions at which silica is kept in solution as water concentrates during evaporation.

Silica is objectionable at high concentration in cooling tower makeup because of this uncertainty about its solubility limits.

Silica is objectionable in feedwater makeup because it may form a scale in the boiler itself, and also because it volatilizes at high temperatures and redeposits on turbine blades. Treatment processes that remove silica are:

- Adsorption on magnesium precipitates in the lime softening operation.
- Adsorption on ferric hydroxide in coagulation processes using iron salts.
- Anion exchange in the demineralization process.
- Precipitation/adsorption from acid solutions onto fluidized limestone containing alumina.
- Seeded slurry R.O. and evaporation.

In mining and mineral processing environments, silica enters the scene in several ways, including the following examples:

1. At a Chilean copper recovery operation, silica can build up to 500 ppm in acidic recirculating process water also containing copper. At this level, H_3SiO_3 (silicic acid) is close to saturation. The pH of the solution is around pH 3.

   Straightforward lime addition to a high pH will not do much good because the solubility of silica appears to have reached a minimum at pH 2 to pH 9, and pH increase from 3 to 8 or 9 will not reduce silica below this minimum. Above pH 9, silica solubility starts to increase again.

At the Chilean copper plant in point, a flow of 8,000 gpm is treated for silica removal. A fluid bed crushed limestone system is employed using limestone with a relatively high $Al(OH)_3$ content. The Al content of this limestone is critical and if the available limestone has a very low Al content, $Al(OH)_3$ can be added separately to the slurry. In the same process, Cl^- is reduced from 100 ppm to 50 ppm. SiO_2 removal from solution appears to occur where the aluminum hydroxide hydrolizes at around pH 3.5. Limestone neutralizes acid at around pH 4.5. Alumina in the limestone dissolves in the acid mine drainage at about pH 3 and then reprecipitates in an active form at pH 3.5 as the limestone dissolution increases the pH. The alumina precipitated in this way is an active adsorbent for SiO_2.

If inadequate alumina is present in the limestone slurry, then silica will pass through the system.

More information on silica removal from acid solutions by fluid bed limestone slurries containing alumina may be available from:

2. <u>ELLIOT LAKE URANIUM - See Appendix I</u>

At Elliot Lake, underground uranium mining operations are not permitted to recycle minewater underground. Water is used in sprays to supress siliceous dusts generated by underground operations, and recirculation of water underground would save pumping costs and also would lead to higher tenor uranium levels in the minewater which constitutes a secondary recovery. At first glance, the Ontario Ministry of Labor disallowment of water recycling because of an enhanced silicosis risk to mineworkers was construed as being due to an increased level of silica building up in the recirculated water. In fact, however, silica levels in the

minewater remain below 10 ppm. The increased $CaSO_4$ levels in recycled solutions, however, could result in fouling of the water sray nozzles which would choke off the supply of water for dust suppression. Another problem could result if mineworkers were to drink the water with elevated gypsum levels resulting from water recycling. The "silicosis risk" due to water recycling underground has nothing to do with silica levels in the water. More definition of the rules may be available from:

3. RÖSSING URANIUM - See Appendix I

Dissolved and colloidal silica level buildup in acid and alkaline uranium leach solutions present a problem in uranium extraction circuits. It is believed that silica levels have an influence on the degree of CRUD formation in SX circuits. Silica also builds up on filter cloths and on ion exchange resins in uranium plants. Every so often, remedial measures must be applied at many operations to remove silica from filter media and resins. The usual process is to apply hot solutions of caustic soda to dissolve silica. Such processes, however, result in osmotic shock to the resin which results in an increased resin degredation rate.

CIX barren solution tenor of 5-15 ppm U_3O_8 and a 1984 recovery into eluate of around 92% is poor by comparison with most plants around the world. The performance of the IX plant has been under scrutiny ever since the operation started, and some of the factors that have been examined are TDS buildup in the preg solution, SiO_2 fouling, ore type, and manganese levels in solution.

SiO_2 in the preg solution has increased steadily since 1980.

	March 1979	February 1984
SiO_2 (ppm) in Preg Solution	427	950

Resin regeneration frequency has been increased to keep SiO_2 levels on resin below 2,000 ppm. The cost of regeneration with 4% and 1% NaOH solutions is high, and the regeneration frequency had been relaxed without serious impact on silica loading. In this way, the cost of regeneration had been cut by 40% since 1983 by optimizing frequency and procedure. The SiO_2 level in pregnant solutions has increased as a result of the increased use of recycled solutions at Rössing as a water saving device. It is likely that some of this SiO_2 passes through the CIX system in the eluate to the SX plant where it may end up in CRUD.

Rössing ore contains variable amounts of cordierite gneiss containing phrrhotite which seems directly related to barren loss of uranium and SiO_2 levels in the pregnant solution. Certainly, the recycling of return dam solution has an influence on SiO_2 in the pregnant solution and, therefore, on the relative merits and costs associated with different resin types.

It is believed that the rate and degree of SiO_2 pickup from solution varies from resin to resin and that in the case of an operation such as Rössing, the effect of SiO_2 uptake on U_3O_8 recovery and on the cost of resin regeneration is significant enough to become a factor in resin selection.

4. JABILUKA URANIUM, NORTHERN TERRITORY, AUSTRALIA

LEVINS (1979) reported 30-150 ppm Si in acid tailings/raffinate from Alligator Rivers-type uranium ore in Northern Territory, Australia. It is not known whether this was a laboratory-derived test or whether the sample analyzed was collected from an actual operation which was recirculating tailings solution to the process.

5. COCA MINES HOG HEAVEN FLOWSHEET

LITZ and SEETON (1984) described testwork of a refractory siliceous silver ore from the Hog Heaven mine district of Coca Mines in Montana. By pretreating ore with 5 Kg NaOH/t in a hot solution, a remarkable improvement in cyanidation recovery of silver resulted. This is believed to be largely due to the unlocking of silica and jarosite encapsulated silver in the ore, possibly by dissolution of silica by the hot NaOH solution and possibly due to alteration of the jarosite structure or liberation of silver locked in alunite. When using two-hour 40°C pretreatment by NaOH solution, the most critical variable found in tests was the consumption of added sodium hydroxide. When all the data points for pretreatment of East Zone oxidized composite ore are plotted against NaOH consumed, it is found that when the consumption of NaOH during pretreatment exceeds 20 kg/t, the residual silver will be less than 30 g/t and in excess of 80% dissolution achieved in the cyanide leach step.

An interesting phenomenon in treating the East Zone test composite is that if NaOH is added in the grind, silver leach recoveries remain poor even when additional NaOH is subsequently added and the pulp heated. Could this possibly have anything to do with thiosalt generation?

Although it is somewhat of a wild speculation, one factor to consider in the flowsheet proposed by LITZ and SEETON (1984) is the fate of dissolved solids and especially, dissolved silica which could likely build up in recirculating solutions in the proposed flowsheet. It is not known whether the effect of solution recirculation was tested, but the chances are good that they were not since this is seldom the practice in

most precious metal bench scale testwork. Not all of the Hog Heaven ores responded positively to hot sodium hydroxide pretreatment.

If scrutiny leads to the conclusion that silica is in fact taken into solution by the proposed process, some consideration will have to be given to how it can be prevented from building up to levels that eventually interfere with metallurgical recovery.

6. Although, in the above cases, the ill effects of silica in ores and in process solutions have been discussed, it is noted that the Rand Water Board doses sodium silicate (waterglass) to Vaal Dam water as a coagulant for the removal of suspended metal precipitate and suspended solids. Silica is likely to help remove aluminum from solution, too, at the appropriate pH range as an alumino-silicate.

7. The NALCO Water Handbook (1979) discusses the removal of colloidal materials such as silica from water. The charge of colloidal materials (1 micron to 0.01 microns in size) is influenced by pH, so for adsorption processes to succeed, careful control of pH may be needed. It is possible for a sudden increase in pH to cause colloidal matter to desorb, rendering a poorer effluent quality than the influent.

   Although some silica in water exists as the bisilicate ($HSiO_3^-$) anion, it is likely that it is for the most part present as a negatively charged colloid. It can be removed by anion exchange in a demineralizing system, suggesting that is ionic; it can also be adsorbed on precipitated iron hydroxide and magnesium hydroxide following an adsorption isotherm which suggests that SiO_2 is colloidal.

8. UNDERGROUND HYDROPOWER, WITWATERSRAND

   In South Africa, the Chamber of Mines Research Laboratories has developed, in conjunction with a major engineering company, a hydraulically powered rockdrill that is considerably more productive than conventional pneumatic rockdrills. 95% water and 5% additives are used as the hydraulic fluid, and hydraulic pressure is provided by the head between the mine working face and the surface. The recirculated water can also be refrigerated on the surface to aid in mine cooling. In order to reduce abrasion on these hydraulic tools, it is important to remove quartz particles which could get into the hydraulic fluid as it is recirculated in the mine environment. Some of the abrasive quartz is present in extremely fine angular particles in suspension in the fluid, and these cannot readily be settled in a clarifier. RANDOL INTERNATIONAL LTD. has identified several cross-flow filtration devices that likely can remove this silica from the aqueous hydraulic fluid, although no such application has hitherto been identified either in bench scale tests nor in commercial use. RANDOL would be pleased to discuss this new idea and possibly arrange for test equipment and consulting expertise to carry out tests for sponsors of this study.

CHAPTER 50

SILVER

The concentration of silver in an unfiltered water sample should not exceed 0.1 ug/l to protect aquatic life according to ONTARIO (1979).

Silver occurs in the native state and as a sulfide as a constituent of a great variety of minerals with sulfur, antimony, arsenic, tellurium, and selenium. The average silver content of soils is about 0.1 ug/g, and certain coal ash contains 2-10 ug/g Ag.

Silver halides such as silver iodide and silver chloride are relatively insoluble in water in contrast to silver nitrate. A comprehensive review of the sources, use, distribution, losses to the environment, and human health aspects of silver have been prepared by CARSON and SMITH (1975).

Sources of silver to the environment include photographic processing, industrial electronics, cloud seeding with silver halides, municipal effluents, and mining and milling effluents and wastes. CARSON and SMITH (1975) indicated that effluents from various municipal wastewater plants indicated silver concentrations of 0.05-45 ug/l.

The greatest concentration of silver was in the Colorado River basin where it was observed in 18% of the samples at a mean concentration of 5.8 ug/l. In the St. Lawrence River, concentrations in water from inshore intake pipes range from non-detectable to 6 ug/l with a mean of 2-6 ug/l, the latter levels considered by ONTARIO (1979) to be possibly suspect, i.e., possibly faulty analyses.

Both the U.S.A. (EPA) and the Canadian Government recommend a limit of 50 ug/l for domestic water supplies based on various human symptoms including blindness, lung malfunction, and skin discoloration due to prolonged ingestion.

Bacteria and fungi growth is inhibited, depending on type between 10-500 ug Ag/l.

Silver is very toxic to plants, even at levels below 1 mg/l.

Invertebrates are also sensitive to silver. Daphnia magna LC50 (24 hours) was 19 ug/l silver and, after 60 hours, 50 percent of Daphnia magna were immobilized at a concentration of 3.2 ug/l silver.

96-hour LC50's for shellfish, e.g., hard clams and the New England oyster Crassostrea Virginica, were 21 and 5.8 ug/l respectively.

Rainbow trout exposed from the egg stage over a two-month period resulted in total mortality of all fish at 2.5 ug/l and greater silver levels and even at 0.6 ug/l, there was a reduction in growth.

It is clear that many natural silver compounds are relatively insoluble, but that concentrations below the solubility limit are toxic to fish. Because of the extreme toxicity to fish over long-term exposures, an objective of 0.1 ug/l total silver for protection of aquatic species was recommended by ONTARIO (1979).

This investigation did not examine silver removals to such ultra-low levels from mine-mill effluents.

A review of silver levels in effluents and leachates from mine-mill wastes undertaken by PEDCO ENVIRONMENTAL, INC. (1983) for the EPA showed:

The PEDCO (1983) study did not flag any mine-mill effluents or solid waste leach tests as not passing the EP toxicity test. For silver, the lowest level category used was 0.05 mg/l Ag which is the primary drinking water standard.

An examination of the PEDCo results indicates that silver in tailings pond effluents ranges from LT 2 to 346 ug/l. Caution should be exerted in discharging solutions with typical tailings pond silver concentrations to fishery-supporting streams if the ONTARIO (1979)

objective of LT 0.1 ug Ag/l is to be met. However, nearly all the samples were, without dilution, below the primary drinking water standard of 50 ug/l.

In disposing of barren bleeds and cyanide leach tailings from silver and gold-silver operations, clearly silver may be a greater environmental problem than generally recognized.

References 2999

At mine-mill operations which treat sulfide ores or even "oxidized" ores with some sporadic sulfide content, it is not uncommon for soluble sulfides and a range of oxidation products of sulfides to occur in mine and process waters. The whole range of sulfur oxidation products from sulfide, sulfur, sulfite, thiosulfate, polythionates, and sulfate have been encountered in mine-mill environments. Of course, all of these except sulfur occur in solution, and sulfate and sulfide may form precipitates with metal cations. Elemental sulfur may be formed from sulfates and sulfide species and may occur as an aqueous suspension.

A most common source of sulfate in water is acid mine drainage which is a common phenomenon in underground mines as well as open pit mines. Sulfates are also generated from sulfide minerals in waste-rock and tailings ponds as described in the section on acid mine drainage.

Generation of thiosulfate, sulfide, ions, polythionates, and elemental sulfur in mine-mill waters and pulps is an area about which operators still know far too little. Very often, metallurgical problems are encountered which are not understood and which may be the direct or indirect result of these species which can be present in solution or in pulps without the operator being aware of their presence. Knowledge of how to inhibit or modify their formation or of practical ways to remove these species when their presence is found to be detrimental is still sadly lacking, as is quantitative knowledge of how they affect many metallurgical processes.

Of course, it is known that cyanide-soluble base metal and iron sulfide minerals in gold and silver ores result in higher cyanide consumption and may interfere with the carbon adsorption of gold and silver and may deplete oxygen levels in cyanidation pulps. On the other hand, soluble sulfide addition to pregnant solutions containing gold, silver, and base metals is advocated as one way to enhance gold adsorption on carbon by removing silver and troublesome base metals such as mercury as a sulfide precipitate before the solution comes into contact with carbon.

Sulfur dioxide is a common conditioning reagent in complex sulfide ore flotation operations, but how well are the reasons for its use known and the requirements for optimum results quantified? Does it contribute to downstream thiosalt problems in effluents?

Thiosulfate is generated in mineral processing plants when ores containing certain types of sulfide minerals are milled at a high pH. Thiosulfate and polythionates formation may be enhanced when SO_2 is added at certain eH conditions at a high pH. Polythionates are simply the polymerised form of thiosulfate.

As far as understanding the chemistry, generation, and treatment of thiosalts in milling effluents, the best summary has been provided by WASSERLAUF and DUTRIZAC (1982). Their report summarizes an extensive evaluation program by CANMET in conjunction with NORANDA MINES LTD. with emphasis on thiosulfate generation at BRUNSWICK MINING AND SMELTING CORP. LTD. in New Brunswick. One of the authors of this report who was deeply involved in the investigation, Mark Wasserlauf, has recently relocated to a consulting company, so three prominent sources of knowledge on thiosalts who have huge volumes of information and experience on the subject are:

Their paper also describes methods for thiosulfate determination.

CANMET found that generation of thiosalts in milling circuits depends mainly on:

1. pH of the pulp and the type of alkalinity reagent used.
2. Sulfide content of the ore.
3. Residence time during flotation.
4. Temperature.

Mass balances were conducted at two New Brunswick mills to define the thiosalt production during various investigations by NORANDA (1977). COTTON, et al. (1977) indicated that some thiosalts in a ground pulp may originate from oxidized surfaces in the ore. Within the range of size distributions normally produced in grinding circuits, fineness of grind was found to have a small effect on thiosalt generation during the grinding operation itself and subsequent flotation. The relative amounts of thiosalts originating from grinding and from flotation in a concentrator apparently depend largely on the pH of the two steps. Other factors found by NORANDA to contribute to thiosalt formation were:

- Sulfide content of the ore; with five times the thiosalts generated by ores with 80-90% sulfides compared with 25-30% sulfides ore.
- Thiosalt generation more than doubles from 25 to 40°C'.
- Increased agitation in flotation results in greater thiosalt formation.

ROLIA and BARBEAU (1979) studied the generation of thiosalts in a continuous process development (pilot) mill at CANMET. The total amount of thiosalts generated was 959 g/t of ore which was comparable with 1021 g/t ore generated in the No. 3 flotation line at BMS before upgrading. A breakdown of thiosalt generation was as follows:

Operation	% of Total
Grinding	17.6
Conditioning	37.0
Scavenging	45.5
TOTAL	100.0

STEGER (1979) investigated the effect of pH, particle size, and airflow on the formation of thiosalts in aqueous suspensions of pyrrhotite, pyrite, chalcopyrite, galena, and sphalerte and found that an increase in temperature or pH of a suspension resulted in increased sulfate and thiosalt generation. A decrease in particle size of mineral also resulted in an increase in sulfate and thiosalt generation. Changes in airflow had a marginal effect.

ROLIA (1980) tested the generation of thiosalts during agitation of pulps on a variety of samples in a flotation cell and found a correlation between sulfur content and thiosalt production. No evident correlation was found between iron content and thiosalt generation.

ROLIA (1977) investigated the production of thiosalts during grinding of pyritic ore from the Brunswick Mining and Smelting No. 12 mine and found that:

1) Thiosalts are produced during mixing of coarse ore (minus 10#) with water prior to any grinding. The amount generated increased directly with mixing time.

2) Thiosalts diminished by two thirds during grinding with steel balls and billets at the natural pH 8 of the ore but increased during grinding with pebbles. This is probably due to either scavenging of oxygen by abraded iron or the reduction of thiosalts by iron.

3) There is an increase in the production of thiosalts with pH over the interval 9.4-10.7.

4) Less thiosalts are produced per unit weight of ore during grinding at higher pulp densities than at lower pulp densities.

5) A direct logarithmic relationship was found between the amount of thiosalts generated during grinding and the grinding time.

6) Significantly, reduced thiosalt generation (86%) occurred during grinding at pH 10.7 in a solution deaerated with nitrogen gas indicating that production of thiosalts was depressed by exclusion of oxygen. Sulfite appeared as the principal sulfur species in the deaerated solution.

Typically, when calcium is present, the gypsum level in solution before it precipitates out is around 2,000 mg/l. However, gypsum has a habit of forming supersaturated solutions and when appropriate "sequestering agents" are added, it is possible to increase the $CaSO_4$ level that a solution will carry to perhaps three times that level. This requires additions of chemical reagents, however. In flotation mills, seldom does the $CaSO_4$ level build up to saturation levels.

It has been found in acid mine drainage occurrences that the presence of magnesium in solution will inhibit the precipitation of gypsum, and much higher levels of sulfate can be held in solution in the presence of calcium ions--way in excess of the solubility product of gypsum.

HOFFMAN (1984) described one such case at the Shullsburg, Wisconsin, zinc mining district on which more information is included in Appendix I. In addition, it is rumored that several years ago a Na_2SO_4 effluent from a base metal recovery plant at Rustenburg seeped from a pond into the pyroxenite rocks below during which it leached magnesium from brucite, talc, and aragonite minerals. It is also believed that high magnesium levels in the underground minewater resulted in metallurgical recovery interference in the flotation plants that recover a copper-nickel sulfide concentrate which carries the platinum group metal primary products.

Even though the Na_2SO_4 seepage occurred from an operation outside the jurisdiction of any of the platinum producers in the area, the platinum mining and recovery companies were unwilling to discuss or confirm this interesting phenomenon due to the proprietory nature of their technology.

Polythionates are not uncommon in sulfuric acid uranium leach liquors and even at relatively low concentrations; these cause a problem by adsorbing onto ion exchange resins resulting in the blinding of resin pores. In some ion exchange systems, occasionally downtime has been attributed to rapid corrosion of stainless steel internal screens by "polythionates." Difficulties also arise when these polythionates convert to elemental sulfur on the resin beads which would clog the pores of the resin. This sometimes occurs when chemical processes are used to try and remove polythionates from resins.

Experts on ion exchange technology that are familiar with polythionate problems include:

ANTON R. HENDRIKSZ
Bechtel Civil and Minerals

San Francisco, CA

High concentrations of thiosalts in recycled tailings decant solutions are believed to interfere with the efficiency of the separations in the flotation plant. But where are the quantitative insights into the mechanisms for this?

At least one major new complex sulfide flowsheet was based on the belief that hexavalent chromium can safely be used as a flotation reagent because all excess Cr^{VI} would be reduced to Cr^{III} in the tailings and tailings decant solution due to the presence of thiosulfate in the pulp. NEWMONT MINING COMPANY's experience in Colorado at their Idarado Mine, which is a subject of CERCLA (Superfund) litigation, would suggest otherwise. Groundwater downstream from the Idarado tailings was found to contain hexavalent Cr in excess of safe drinking water standards.

Addition of soluble sulfides may sometimes be used to form a sulfide coating on oxidized base mineral particles rendering them amenable to froth flotation recovery by making them behave relative to collectors and frothers as a sulfide mineral particle.

It has been speculated that the presence of excessive sulfate in process solution can coat lead mineral particles with a thin layer of insoluble lead sulfate which makes these particles less amenable to flotation as a sulfide.

In tailings dumps containing sulfide mineral particles, usually the ubiquitous pyrite, pyrrhotite, or marcasite, oxidation of sulfides continues steadily for many years after the tailings pile has been deposited. When a cut is made through such tailings ponds after they are drained, be they sand or slimes, it is clearly evident that they contain zones with a wide variety in degree of oxidation and pH across the exposed cross-section of these tailings. Reclamation and retreatment of such tailings, for example, for gold cyanidation recovery may present metallurgical surprises.

Acid mine drainage is becoming recognized as a much more serious and common problem which is a feature of tailings and wasterock piles from just about every mine-mill operation that treats materials containing sulfides. The huge uranium recovery operations around Elliot Lake generate vast tailings impoundments containing 2-4% sulfide. In time these become a major source of acid which will require neutralization before seepage and runoff can legally be discharged for centuries to come. The massive sulfide ore deposits that occur across the Canadian shield and also in the western part of Canada yield tailings and wasterock that will also generate acid and sulfate for hundreds of years to come unless a better answer to their permanent disposal can be developed. The South American copper mines and Witwatersrand gold-uranium tailings all generate AMD containing sulfate as the most common anion. Of course, considering the widespread distribution and magnitude of coal mining and the ubiquitous presence of pyrite and other sulfur species in the coal waste, this industry presents the largest AMD problem.

The presence of sulfate in mine-mill effluents is used to advantage in the removal of radium from uranium mill effluents. Addition of barium chloride results in precipitation of $BaSO_4$ which coprecipitates radium as $\underline{BaRaSO_4}$.

When sulfate is present in solutions, e.g., reclaimed railings dam water recycled from tailings ponds containing sulfide-bearing materials, or from gypsum waste disposal sites (e.g., at Florida phosphoric acid plants), then where calcium is introduced to the system (as lime for pH control or as a constituent of the ore), a serious gypsum scale problems can result. The inhibition of gypsum scale formation by addition of reagents is a significant business opportunity for companies such as:

- NL Industries, Barochem Division
- Nalco
- Calgon Corp.
- Drew Chemicals

A wellknown gypsum scale inhibitor is sodium hexa meta phosphate, but there are others (cresylic acid?).

ENVIRONMENTAL IMPACT OF SULFATE AND THIOSULFATE

Sulfates, per se, are not generally considered detrimental to the environment unless their level exceeds a certain threshold which is in the thousands of mg/l range. At extremely high levels of sulfate, the water is rendered unsuitable for public water supply use and for livestock watering. The reason is that high sulfates cause humans and livestock to get the "trots."

Examples where this has occurred, for example, include the initial operation of the water treatment plant at Kromdraai Coal Mine, near Witbank, Transvaal. High density sludge decant water product was used to supply a nearby army base and soon had the army "on the run." Sulfate levels are around 2,000 ppm.

HOFFMANN (1984) described the Shullsburg, Wisconsin, water quality changes in well water after Eagle Picher closed down their zinc mines in Wisconsin.

Apart from the sensitivity of certain plant species to high sulfates in water and the catharsis effects mentioned above, the environmental impact of sulfides up to say 1,000-2,000 ppm is not known to be of major concern. Livestock can survive (not optimally perhaps) on water with TDS up to 10,000 if the TDS is mainly Na and Cl^-. When levels of other ions are high, e.g., $SO_4^=$, etc., perhaps the TDS level is reduced to 5,000 ppm, but no firm data was found.

REGULATORY LIMITS: SULFATE, SULFIDE, AND SULFUR COMPOUNDS

During the course of this investigation, no direct regulatory limits were encountered for sulfate and thiosalts, e.g., thiosulfate, thiosulfate and sulfur. However, there are indirect water quality limits that can be impacted by the presence of sulfides and thiosalts. For example:

1) At very high concentrations of sulfide ions, certain metal ions will become solubilized as sulfide complexes and may be difficult to precipitate.

2) Most effluents must meet certain pH limits before they can be legally discharged. When thiosulfate is present in an effluent, it may oxidize downstream to the extent that the pH of the receiving waters is lowered below permissible limits. A wellknown example where thiosulfate oxidation results in pH reduction is in the New Brunswick massive sulfide flotation operations in eastern Canada.

In drinking water, (SOUTH AFRICA, 1971), the recommended and maximum allowable limits for sulfate (as $SO_4^{=}$) are 250 ppm and 400 ppm respectively. Recommended tds and maximum allowable limits are 500 and 2,000 ppm respectively.

The South African Water Act (Act 54 of 1965) has recently been ammended. The Dept. of Water Affairs has been renamed the Dept. of the Environment, and it has promulgated a series of measures to protect water quality, several of which will have a major impact on mining operations in South Africa. Although sulfate concentration is not directly impacted, the new regulations are believed to have included an upper limit for TDS expressed in milliSiemens per m at 300 mS/m. This is the equivalent to aboout 2,000 ppm TDS.

Section 22 of the Water Act has been amended as follows:

> "Any person who has control over land on which anything was or is done which involves a substance capable of causing water pollution, whether such substance is a solid, liquid, vapor, or gas, or a combination thereof, shall take such steps as may be prescribed by regulation under Section 26 in order to prevent:
>
> - Any public or private water on or under that land, including rainwater which falls on or flows over or penetrates such land, from being polluted by that substance, or if the water has already been polluted, from being further polluted by that substance."

The new amendments also make provision for potentially very onerous forfeiture of profits and compensation to others who have suffered a loss on account of a polluting activity.

THIOSALT DETERMINATION METHODS

CANMET, in 1976 when they became involved in the thiosalt program, found that there are difficulties in taking reliable samples and storing them for thiosalt analysis. This is due to chemical degradation and natural oxidation of thiosalts by thiobacteria. Also, then available analytical techniques were cumbersome and largely unproved, especially on actual mill effluents.

These problems in sampling and analysis led to the conclusion that much existing chemical data on thiosalt levels in mine-mill effluents were questionable.

CANMET has developed adequate sampling procedures and simple but accurate analytical methods. These are simple titrimetric and colorimetric methods capable of determining thiosulfate, trithionate, and tetrathionate separately. Tests by CANMET indicated that freezing offered the best means of sample preservation.

Carbonate, sulfide, and sulfite were found to interfere with simple titrimetric methods as employed by NORANDA (1976) which were simple and rapid and able to measure between 50-5,000 mg/l total thiosalts but were unable to distinguish between individual polythionates.

WASSERLAUF and DUTRIZAC (1976) discuss the following determination methods:

TITRIMETRIC METHODS

Acidimetric Titrations: This is based on the oxidation of thiosulfate and polythionate with mercuric chloride as originally proposed by FELD (1911). After various modifications, the method was further improved by NORANDA (1976), and the method is described in detail by WASSERLAUF and DUTRIZAC (1982). Interferences may be caused by several components of mill waters, e.g., sulfide ions which will react with mercuric chloride to produce acid, but there is an analytical procedure around this. Ferrous iron also leads to high results which can also be avoided. Sulfate also interferes.

Iodometric Titrations: Thiosulfate and sulfite can be determined by classical methods. Two titrations are made: one in the absence of formaldehyde to determine the sum of thiosulfate plus sulphite; and one after addition of formaldehyde to mask the sulfite to determine only the thiosulfate. Sulfite is then calculated by difference. Polythionates are not titrated and do not interfere. Precautions must be taken to avoid air oxidation of the sulfite, especially in alkaline solution if accurate results are needed.

Spectrophotometric: Most spectrophotometric met' ods for polythionates and thiosulfate have been based on measuring the amount of thiocyanate produced after addition of suitable reagents. The thiocyanate is then determined as its iron(III) complex.

Colorimetric analytical methods for thiosulfate, trithionite, and tetrathionate in mill effluents were defined by CANMET. Several other techniques, including titrimetric methods using EDTA and excess barium, were investigated. Also, methods for determination of thiosulfate below 50 mg/l were investigated, but they were subject to large uncertainties. IR and UV thiosalt spectra were measured but in all cases, these methods were found to be unsuitable for routine determination of thiosalts in milling effluents.

TREATMENT FOR REMOVAL OF SULFIDE, THIOSULFATE, SULFATE, AND THIOSALTS

CANMET and NORANDA MINES LTD. have undertaken more work than any other mining company to our knowledge on the thiosalt removal process. WASSERLAUF and DUTRIZAC (1982) "evaluated fourteen methods of thiosalt destruction on technical and economic grounds. Some of these methods, e.g., electrodialysis, were the subject of paper studies only, but most of the techniques were extensively examined at the laboratory level and those such as biological oxidation were tested at pilot scale." They concluded that, "when all aspects are considered, thiosalt destruction costs become very high; furthermore, none of the methods has yet been proved to be continuously effective for the large-scale treatment of actual thiosalt effluents." Numerous reports, technical memoranda, and other documents describing the results of CANMET and NORANDA's six-year program have been issued and may still be available from CANMET. These are listed in Appendix 3A, B, and C of WASSERLAUF and DUTRIZAC (1982).

Natural oxidation of thiosalts occurs relatively rapidly at high temperatures, and all that is needed is a tailings pond and a large holding reservoir for decant solutions in summer and a location with a warm climate. Thiosalt removal becomes a problem mainly in cold climates, particularly where precipitation exceeds evaporation, and discharge of an effluent cannot be avoided.

The methods for thiosalt removal that CANMET evaluated include:

- Chemical Oxidation (Including H_2O_2, Cl_2, O_3)
- Membrane and Electrochemical Processes (Reverse Osmosis, Electrodialysis, and Electro-oxidation)
- Air Oxidation (Alkaline Oxidation, Cu-Catalyzed Air Oxidation, SO_2-Air Oxidation)

SULFUR

- Biological Oxidation (Biological Contactor, Activated Sludge; NORANDA Packed Ponds)

- Other: (Reduction by Metals; Disposal to the Sea)

Estimates of capital and operating costs were developed for most of the methods considered, but the reports urge caution in their use due to the very preliminary nature of the studies.

A summary of the CANMET project results as reported by WASSERLAUF and DUTRIZAC (1982) is inserted below together with a list of pertinent references, again with a caution that the 1982 capital and cost data in Canadian dollars are considered tentative estimates by the authors.

SULFIDE

When ores contain cyanide soluble sulfides, these will consume cyanide and add expense to a gold and silver recovery operation. The pH may also be lowered, and lime consumption will also be increased.

It is standard practice in several gold recovery operations to add lead nitrate or lead acetate to the ore to inhibit dissolution of the sulfide minerals. Examples of operations where a lead salt is added during leaching include:

ECHO BAY MINES
Lupin Project
Northwest Territories
Canada

NEW CONSORT GOLD MINE LTD.
Post Office Noordkaap 1304
South Africa
(01314) 3031
Piet Ferreira
Plant Superintendent

Often ores containing cyanide-soluble sulfide also contain ferrous iron. Such ores are best treated by pre-aeration prior to leaching to achieve better gold leach recoveries. This is particularly important if the pulp is to be treated by CIP because the presence of ferric iron and/or sulfides in solution seems to alter the way in which gold adsorbs on activated charcoal.

Additional lead nitrate is added prior to zinc precipitation as when soluble residual amounts of sulfides are present, and they have been found to inhibit zinc precipitation. The lead salts seem to remove any residual sulfides from solution. A typical dose of lead salt could be as high as 0.30 Kg/t solids as in the case at the NEW CONSORT GOLD

MINE. Sulfide addition in the presence of iron ions will effectively precipitate cyanide from pulps and solutions. This is, in fact, a way of removing cyanide from effluents which was patented by COMINCO.

SULFATE

Sulfate removal is generally not considered necessary or justifiable except for boiler feedwater production or to make a low TDS water for the AARL carbon elution process.

On the Witwatersrand (Johannesburg-Pretoria), currently there is serious concern about the steadily increasing TDS in water pumped from the Vaal Dam. This has been described by KEMPE (1983) who pointed out that about 30% of the dissolved solids reaching the Vaal Dam from point source discharges did so in 13% of the point source discharge volume contributed by acid mine drainage from underground mines. A further undetermined amount of acid mine drainage containing sulfate ions is generated by the many large mill tailings dumps.

Sulfate levels of 3,300 ppm $SO_4^=$ have been measured in the effluent discharged from the ERPM mine on the eastern Witwatersrand according to KEMPE (1983). Seepage from sand dumps are reported at 3,400-26,000 mg/l $SO_4^=$. These levels of sulfate and TDS are higher than those typically encountered in drainage from South African coal mines.

The removal of sulfates may soon become mandatory in South Africa in the context of meeting the limit on TDS. To date, reverse osmosis and electrodialysis reversal have been tested at the Hercules Shaft of the ERPM mine on the eastern Witwatersrand as described in Appendix I.

DESALINATION

REVERSE OSMOSIS

NORANDA and CANMET tested a pilot R.O. unit for thiosalt and sulfate removal from Brunswick Mining and Smelting effluent. The results were rather impressive as far as sulfate removal was concerned, but recovery efficiency does not seem to have been mentioned. One major problem with treating $CaSO_4$ containing water by membrane processes is that as the TDS concentration increases in the concentrate, so a point is reached where gypsum becomes saturated and precipitates onto the membrane resulting in fouling. This would normally occur at around 2,000 ppm $CaSO_4$ in acid mine drainage but by addition of additives, gypsum precipitation can be inhibited, perhaps to 6,000 ppm $CaSO_4$. Concentrates would exceed this level after only 80% recovery from AMD containing 1,500 ppm $CaSO_4$. This would also result in a relatively large volume of concentrate to dispose of.

MALAIYANDI and SASTRI (1981) investigated reverse osmosis separation of sulfate, nitrate, and ammonia from mining effluents. Cellulose acetate membranes were characterized in terms of pure water permeability constant, solute transport parameter, and mass transfer coefficient with NaCl solution as the reference system. R.O. behavior of several anions including sulfate were studied in the range 100-300 psi which constitutes a relatively low pressure as far as R.O. systems are concerned, and product water of suitable quality for use in recycle operations was obtained.

A major advantage of R.O. is that if several deleterious contaminants must be removed to render the water reusable in the metallurgical process or suitable for discharge as an effluent, then R.O. can very likely remove all of them with a single processing step.

MALAIYANDI and SASTRI can be reached as follows:

M. MALAIYANDI
Environmental Health Directorate
Health Protection Branch
Ottawa, Ontario
Canada

V.S. SASTRI
Mineral Sciences Laboratories
Ottawa, Ontario
Canada

MALAIYANDI and SASTRI (1981) subjected a sample of Quirke tailings effluent (a uranium mine at Elliot Lake), to reverse osmosis at 300 psig. The product water was analyzed for a series of common pollutants, and the following results were achieved:

QUIRKE TAILINGS EFFLUENT AFTER R.O.

Constituent	Feed Water (ppm)	Product Water (ppm)
Ca	100.0	5.0
Zn	2.0	0.09
Fe	10.2	0.10
Cu	2.0	0.09
Mg	18.0	1.00
NO_3	110.0	47.0
SO_4	1170	88.5
NH_3	22.6	9.1

The metal ion concentrations are within acceptable levels as far as environmental limits are concerned. A comparison of the average concentrations of sulfate and nitrate (1,400 ppm SO_4 and 110 ppm NO_3) in the tailing and levels in the product water (88.5 ppm $SO_4^=$ and

47 ppm NO_3^-) indicate that there is a respective reduction of about 16 and 2.6 times of these species. The sulfate level in the product water is lower than that drawn from the lake (142 ppm $SO_4^=$).

However, the nitrate level in the R.O. permeate is higher than the average level in the lake of 7.4 ppm NO_3^-. The product water was subjected to a second stage R.O. treatment and analyzed at 19 ppm Sulfate, 20 ppm NO_3^-, and 4 ppm NH_3. This water was suitable for recycling purposes. It is interesting to note how difficult it is to remove ammonia and nitrate to below regulatory limits by R.O. using a cellulose acetate membrane. Nonetheless, $SO_4^=$ and metals are very effectively removed.

MALAIYANDI and SASTRI did not show the recovery achieved in their R.O. tests. Considering that feedwater $SO_4^=$ concentration was 1,170 ppm, it would seem that $CaSO_4$ saturation would be reached after recovery of only 50% of the water and if $CaSO_4$ is sequestered after recovery of only 85% of the water in the feed leaving a large volume of effluent with concentrated salt levels to be disposed of. As recovery increases, so the volume of concentrate will decrease, and its level of salt concentration will increase correspondingly. As this occurs, so osmotic pressure will rise, and higher pressures are needed to yield more product. This can be largely overcome by applying a seeded slurry tubular R.O. configuration as discussed below.

BHATTACHARYYA, et al. (1979) described the use of low-pressure charged non-cellulosic membrane ultrafiltration which simultaneously remove dissolved metals and sulfate as well as suspended solids from acid mine drainage water. Of commercially available membranes evaluated, membranes of initial water flux 8.2-17.3 x 10^{-4} cm/s at 5.6 x 10^5 N/m² were most suitable. At the optimum operating pH of 4.0, a channel velocity of 200 cm/s minimized membrane fouling, and concentrated acid mine water containing 16,000 mg/l TDS caused a flux drop of less than 30%. For an acid mine water flow rate of 3,800 m³/d, 90% water recovery was achieved with a membrane having a surface area of 3.0-6.0 x 10^3 m². Ca, Mn, Fe, and Al removals were 50, 73, 98, and 85% respectively.

It was not established where the 3,800 m³/d facility referred to was located. D. Bhattacharyya can, however, be reached as follows:

(606) 257-2798

Results of the EDR and R.O. test demonstration plants at the EAST RAND PROPRIETORY MINES LTD. operation in South Africa (see Appendix I) have not yet been announced. However, it has been established that R.O. using a new configuration known as slurry seeding can achieve in excess of 95% water recovery from gypsum-bearing acid mine water

yielding the following product and a waste concentrate consisting of precipitated solids and a brine concentrate.

	Feedwater	Concentrate Brine	Concentrate Solids	Product
Ca	333 mg/l	440	24.7%	10.9 mg/l
Mg	120 mg/l	1,025	496 ppm	9.3 mg/l
Cl	88 mg/l	380		50 mg/l
SO_4	1,645 mg/l	8,250		112 mg/l
SiO_2	44 mg/l	92	5.4%*	13 mg/l
pH	4.24	4.4		5.22
Conductivity	2,650 ms/cm	12,200 ms/cm		545 ms/cm

* Acid Insoluble (Siliceous)

A flowsheet arrangement describing a seeded slurry reverse osmosis water recovery operation is shown below. The seeded slurry approach employs a recirculating slurry of solids that precipitate from the concentrate which cause supersaturated salts to precipitate preferentially on the solids particles rather than on the membrane surface.

The unit capacity of tubular R.O. modules is much smaller than for other systems such as holofine fiber and spiral wound systems. Consequently, more modules are required when employing the tubular R.O. system to treat a given flowrate. However, by using the seeded slurry process, the need for pretreatment of the feedwater can be dispensed with, and a much better overall water recovery can be achieved, as well as smaller concentrate volumes.

Seeded slurry technology is offered by:

RANDOL INTERNATIONAL LTD. predicts that seeded slurry technology will revolutionize the application of membrane technologies for applications such as acid mine drainage

SYSTEM SCHEMATIC
SEEDED REVERSE OSMOSIS PROCESS

treatment. Another factor in making seeded slurry R.O. economically feasible is the recent development of an improved low-cost tubular R.O. system by BINTECH (PTY) LTD., Paarl, South Africa.

EVAPORATION

At RUSTENBURG, a Na_2SO_4-rich effluent generated in the metallurgical leaching of copper, nickel, and cobalt from a matte is now treated by a multi-effect evaporating cyrstallizer to recover sodium sulfate and water as products.

The sodium sulfate is generated when a sulfuric acid waste stream is neutralized with NaOH. About 50% of the evaporated water is recovered and returned to the process water system. It is of excellent quality with a conductivity typically of 20-30 ms/cm.

When excess evaporator capacity is available, the evaporator is used to treat effluent that accumulated over several years in a nearby pond after it is first treated by lime/soda softening.

In addition, the crystallizer-evaporator treats runoff from the plantsite that contains Na_2SO_4.

The Na_2SO_4 crystallizer plant consists of a Swensson three-stage multi-effect evaporator followed by a centrifuge and air drier which yields a dry crystalline product.

It should be borne in mind that almost all technology related to platinum recovery is closely guarded and regarded as proprietory.

BIOLOGICAL - BACTERIA

Several biological processes have been proposed for sulfate removal from effluents. This is, after all, one of the ways nature purifies water containing metals and sulfates. It must always be borne in mind that numerous biological processes may be occurring at the same time in the same solutions--some may be generating sulfate while others are reducing it.

In discussing biological methods for sulfate and metal removal for treatment of effluents or as a final polishing step, invariably the idea is dismissed on the grounds of, "What assurance is there that metal sulfides generated in the process will be stable and will not reoxidize to produce a contamination problem in years to come?"

There really is no proof or assurance yet that this cannot happen. Nonetheless, biological systems have not been thoroughly investigated to see whether such safeguards can be engineered into a system. EDISON S. BASTIN (1926) reviewed the natural reduction of sulfates in a paper, in which he refers to sulfate depletion in soils and waters of the Black Sea and certain canals in Holland. The reason for this is the presence of sulfate-reducing bacteria which have converted sulfate to sulfide which has precipitated as FeS on the sediments in the lake and canal beds. In fact, the reason for the name Black Sea is the color of these sulfide sediments on its shores.

The reduction of sulfates in natural waters through the action of sulfate-reducing bacteria with the generation of hydrogen sulfide has been observed by many workers dating back to 1886. The situations in which such bacteria have been found include river muds, brackish canal muds, sewage, soils, lake sands, dune sands at depths to 37 meters, black muds of the ocean bottom to depths of 16 fathoms, and bottom muds of the Black Sea to depths of 2,118 meters. Three species of sulfate-reducing bacteria have been isolated and described by the early workers. These include Microspira aestuarii which is strictly anaerobic and was described by VAN DELDEN (1903-1904). Another sulfate-reducing bacteria is Microspira desulfuricans described by KUHR (1921).

Water drained from blue muds taken from the ocean floor by MURRAY and IRVINE (1895) were found to be higher in $CO_3^=$ and depleted in $SO_4^=$ than the normal seawater from which the muds were derived. The gain in carbonate is due to reduction of sulfate by organic matter in the muds and the subsequent decomposition of the alkali earth sulfides by the carbonic acid thus formed to yield alkali and alkalic earth carbonates. Sulfides formed in the process are deposited as FeS.

A thermophilic bacteria, Vibrio thermosulfuricans that flourishes at 55°C' and which grows more rapidly than Micorspira desulfuricans and M-aestuarii, has been identified by ELION (1924-1925). Vibrio thermosulfuricans is morphologically indistinguishable from the other two bacteria and, therefore, is probably an aclimated strain of the other two. A supplementary source of organic carbon may be needed for energy by these bacteria.

STARKEY (1956) reviewed the transformations of sulfur by microorganisms. He found that diverse microorganisms participate in transformations of sulfur, many of which command attention as they result in compounds having objectionable odors or causing destruction of industrial equipment. Incompletely oxidized inorganic sulfur compounds and elemental sulfur are oxidized principally by photosynthetic and chemosynthetic bacteria, but certain heterotrophic microorganisms can also bring about some of the

reactions. Two principal sulfur products are formed--under anaerobic conditions, sulfide is the stable product whereas under aerobic conditions, sulfate is the stable one.

Certain bacteria can oxidize thiosulfate, tetrathionate, and sulfite as well as sulfide and elemental sulfur. The green bacterium Chlorobium thiosulfatophelum, for example, oxidizes sulfide, sulfur, thiosulfate, and tetrathionate to sulfate, whereas Climicola oxidizes only sulfide and sulfur. All the purple and green sulfur bacteria can develop in the absence of petrified organic matter, meeting their energy requirements from light, with carbon dioxide as their only source of carbon, and oxidizing reduced sulfur materials.

The significance of this is that although bacteria do reduce sulfate and thiosalts to sulfur or sulfides, other bacterial processes can reverse the reaction and convert sulfur, sulfite, and thiosalts to sulfate, as do the wellknown thiobacillus ferrooxidans and thiobacillus sulfoxidans.

Inorganic sulfur compounds are oxidized by various heterotrophic microorganisms that develop equally well with or without these compounds. ARMSTRONG (1921) reported oxidation of thiosulfate by several fungi. TRAUTWEIN (1921) described certain cultures that oxidized thiosulfate to tetrathionate. These were found to be heterotrophic bacteria, and this transformation can, according to STARKEY (1956), be brought about by various bacteria, actinomycetes, and filamentous fungi growing on organic substrates.

GUITTONEAU (1927) and GUITTONEAU and KEILLING (1932) found that elemental sulfur was similarly oxidized to thiosulfate and tetrathionate by many heterotrophic bacteria, actinomycetes, and filamentous fungi during development on organic media.

WASSERLAUF and DUTRIZAC (1982) refer to the pilot scale work carried out by NORANDA at Brunswick Mining and Smelting with a view to oxidizing thiosalts to sulfate. Although the process works well on a bench scale, Brunswick Mining and Smelting has not been able to make this process work economically on a commercial scale in the New Brunswick climate. However, possibly a similar system (pebble bed substrate for bacterial support) could be developed for bacterial sulfate removal from effluents. Potential problems include the clogging of pores by accumulations of sulfur° or iron sulfides if the process is operated under anaerobic conditions or if suspended solids settle out in the open spaces of the pebble bed.

To date, there has been no sign of any testwork to develop the use of rotating biological contactors for biological SO_4 removal from solution although an RBC has successfully been demonstrated for oxidation of ferrous to ferric ions in acid mine drainage. To date, not much need has been noted for $SO_4^{=}$ removal in North America where RBC technology has developed. RBC's might prove useful in the context of South Africa's need to remove sulfate from Witwatersrand effluents.

Several other bacteria types are also known to reduce sulfate including Desulfovibrio desulfuricans and Desulfotomaculum. However, to date, no engineered system to use these has been tested to our knowledge.

SPISAK (1979) reviewed current research of the sulfur metabolic symbiosis of Desulfovibrio desulfuricans and Chlorobrium thiosulfatophilum, which sheds some light on the chemistry changes of solutions in contact with these bacteria.

Another worker in this field is HERRICKS (1982) who evaluated two biological methods for the treatment of acid mine drainage. The first was the treatment of impounded AMD through the addition of a mixed microbial community and C sources appropriate for their maintenance. In the second method, an anaerobic digestor provided waste liquors high in organic acids. AMD was mixed with the digestor effluent in an anaerobic reactor which

maintained SO_4^{2-} reduction. The utility of a pilot plant design incorporating anaerobic digestion, SO_4^{2-} reduction, and final clarification and settling was demonstrated.

CORK (1985) described a two-step bioprocess for converting gypsum to sulfur. The bioprocess is completely aerobic and consists of an immobilized whole cell reactor coupled to a light efficient bioreactor. The first step of the single-stage reduction, single stage oxidation process is catalyzed by an acetate degrading, sulfate reducing microorganism. The second stage "gas to liquid" phase biocatalysis converts H_2S and CO_2 to acetate. The acetate from the second step is used to reduce sulfate in the first step. An economic analysis by the author indicates that the cost of the sulfur produced is dependent on the price of efficiently utilizing electrically generated light and establishing other marketable bioproducts. Once again, a careful examination of the economics of innovative processes such as this is called for as little data is currently available to provide a frame of reference.

WAKAO, et al. (1979) described a process for treatment of acid mine water using sulfate-reducing bacteria at the abandoned Matsuo sulfur and iron sulfide mine in Japan. The acid mine water containing sawdust was used as a basic culture medium. Vigorous sulfate reduction and neutralization of the acid mine water occurred in the batch cultures supplemented with an organic nutrient, either peptone, sodium formate, sodium lactate, or sodium pyruvate. Sulfate reduction evidently did not occur below pH 4 but started only when the pH of the culture rose to the range 4-5.2, possibly through the activity of other heterotrophic microflora. Neutralization of the acid minewater (pH 4) by sulfate reduction was also possible in the continuous flow system if organic nutrients usable by bacteria were supplemented, and the flow rate of effluent was properly controlled.

TUTTLE, et al. (1968, 1969) showed that mixed cultures of sulfate-reducing bacteria could reduce sulfate ions and increase the pH of acid mine water when supplied with wood dust, degradation products of which served as carbon and energy sources for the bacteria. DECKER and KING (1973) also showed that the introduction of an organic energy source (waste water sludge) into an acid strip mine lake will substantially hasten the recovery of the lake.

SISLER, et al. (1977) showed that the rate of neutralization of acid mine water by sulfate reduction would increase electrobiochemically if electrodes connected with an external conductor were placed in the bottom sediment and also near the surface in the overlying water at pH 3 or above.

WAKAO, et al. (1979) concluded that sulfate-reducing bacteria are obligate anaerobes, and therefore their growth and activity are significantly influenced by the oxidation-reduction potential of the environment. Sulfate-reducing bacteria have been reported to require an environmental Eh value of below-200 mV for the initiation of growth (ZOBELL and RITTENBERG, 1948; ZOBELL, 1959; and POSTGATE, 1959).

Hydrogen ion concentration is a limiting factor of bacterial sulfate reduction in acid mine water because the growth and activity of sulfate-reducing bacteria were favored by neutral or slightly alkaline conditions pH 6.5-7.5 but were retarded by acidic conditions according to ZOBELL (1957), KIMATA, et al. (1955); TEZUKA (1965); and ABD-EL-MALEK and RIZK (1963). WAKAO, et al. (1979) found that sulfate reduction failed to occur below pH 4 and started when the pH of the culture reached 4-5.2, irrespective of the initial pH. The initiation of sulfate reduction in acid mine water requires an increase of pH to the threshold value of 4-5.2 either by the activity of other heterotrophic bacteria or by the addition of neutralizing agents. A higher initial pH increases the sulfate reduction rate by decreasing the lag period. Once started, progress of sulfate reduction in the acid mine water results in an increase in pH to neutral or alkaline values, probably due to the formation of alkaline species such as bicarbonate in addition to the formation of sulfides from sulfate (ABD-EL-MALEK and RIZK, 1963; and ABD-EL-MALEK and RIZK, 1963a).

It is also wellknown according to WAKAO, et al. (1979) that only a few compounds such as lactate, pyruviate, malate, and formate are utilized by sulfate-reducing bacteria as carbon and energy sources for sulfate reduction (TEZUKA, 1965; SATO and HATTORI, 1961; CAMPBELL and POSTGATE, 1965; and POSTGATE and CAMPBELL, 1966). Sulfate reduction works in cultures supplemented by peptone, wheat bran, or glucose because of synergisms between sulfate-reducing bacteria and other heterotrophs. WAKAO, et al. (1979) point out that sulfate-reducing bacteria commonly occur in close association with other hetrotrophic bacteria, and the latter decompose a wide variety of organic compounds, including carbohydrates, amino acids, peptone, organic acids, and alcohols with the formation of essential nutrients for the growth of sulfate-reducing bacteria (TEZUKA, 1966; TEZUKA and KITAMURA, 1963; TEZUKA, et al., 1964; TEZUKA, 1964; KIMATA, et al., 1955; and WAKAO and FURUSAKA, 1976). Therefore, the addition of sufficient amounts of readily decomposable organic compounds to acid mine water enables the sulfate-reducing bacteria to develop and reduce sulfate in the presence of a mixed bacterial population. This may prove to be a limiting factor unless a large quantity of low cost organic materials suitable for the purpose can be found near the location of the acid mine drainage treatment need.

It has been generally thought that various metal ions inhibit the sulfate-reducing bacteria, but very little is known about this. At the Matsuo Mine in Japan, described by WAKAO, et al. (1979), there is some Cu^{2+} in the acid mine water. WAKAO, et al. (1979)

found that Cu and Zn do not suppress the sulfate reduction by bacteria contrary to the findings of others (KIMATA, et al., 1955; POSTGATE, 1965; and DOWA MINING (1974).

WAKAO, et al. (1979) conclude, however, that the inhibitory effects of various metallic and inorganic ions (Cd, Pb, Hg, Mn, Al, As, etc.) which occur in minewater should be investigated to learn more about the sensitivity of sulfate-reducing bacterial processes to metal contaminants.

WAKAO, et al. (1979) attempted to establish sulfate reduction on a continuous flow basis. The pH of the effluent solution after it had passed through the sawdust culture remained neutral, and virtually all iron was removed as a black sulfide. When the pH was kept at four in the influent mine water, sulfate levels were significantly reduced. Once the pH was allowed to drop to three, however, a steady sulfate reduction was not established, and the sulfate levels in the effluent increased while pH dropped with time.

The continuous flow experiment in which organic nutrients were added to the water showed that sulfate can be reduced if adequate nutrients are supplemented.

WAKAO, et al. (1979) envisage a series of ponds supplemented with organic matter to treat acid mine water from the abandoned Matsuo Mine. However, they point out the need to solve the possible problem of iron sulfide re-oxidation to generate sulfate once the precipitates leave the anaerobic fermentation system. They feel that some treatment will be needed to remove excess hydrogen sulfide as well as FeS from the system. They suggest that this might be possible using anaerobic photosynthesis bacteria capable of oxidizing hydrogen sulfide to sulfur as proposed by CORK, et al. (1978) and CORK (1985).

WAKAO, et al. (1979) indicated that they will further investigate the applications of bacterial sulfate reduction and sulfide oxidation by photosynthetic bacteria to a purge process for acid mine water in the field. More information may now be available from:

In Colorado, an interesting, possibly related phenomenon has been observed in which a mountain stream in its upper reaches is polluted by base metal acid mine drainage. However, after being filtered through a series of beaver dams, the lower reaches support native trout. This observation was made by one of the engineers employed by the Colorado Dept. of Health who advocated research into the development of passive treatment systems.

In seeking expertise on biological processes and their applicability for mining industry effluent treatment, sponsors are referred to the following consultants:

In addition to examining bacteria, possible development of the algae Oscillaria and Ulothrix may have potential in sulfate removal. These attached filamentous algae have, for a long time, been recognized for their ability to decompose calcium sulfate to sulfur and H_2S, but very little is known about the conditions under which this process is optimized.

CONCLUSIONS: BIOLOGICAL PROCESSES

In conclusion, it must be emphasized that biological sulfate, thiosulfate, and thiosalt removal processes are still in the early stages of conceptualization. There are numerous technical aspects to be resolved and, most importantly, to date none seems to have quantifiable data on the economics of these processes. For example, what size ponds are needed, how much organic nutrient supplement is required and at what cost, and how much electric power is needed for photosynthetic processes? No doubt the economics and applicability of biological processes will vary greatly with location and site-specific conditions, including climatic constraints.

CHEMICAL PROCESSES

SOIL GEOCHEMICAL ATTENUATION

CRONCE, et al. (1980) described a test in which acid water was applied weakly at three levels (0, 12.5, and 25 m^3/week) to an unlimed and a limed (20 t/hr) floodplain soil. Soil water samples were collected weekly at soil depths of 25, 75, and 130 cm. The soil water samples and the acid water were analyzed for pH, total acidity, Al, Fe, Mn, K, Ca, Mg, Na, and $SO_4^=$. The effect of liming, levels of acid water irrigation, and depth in soil profile on the soil water quality were determined. Initially, both the unlimed and limed areas had a considerable capacity for renovating the applied acid water. However, with time, lower pH values and higher levels of Al, Fe, and Mn were found at 25- and 75 cm soil depths in the unlimed areas. When the soil was limed, the soil water at 25 cm depths was nearly neutral or alkaline throughout the study and practically devoid of Al, Fe, and Mn. At the 130 cm depth on both unlimed and limed areas, the pH, total acidity, Al, Fe, and pH of the soil water remained relatively unchanged, even after 525 m^3 of acid water had been applied. The growth of ryegrass and tall fescue was not adversely affected by irrigation with the acid water but was significantly increased by liming. The tall fescue yield was significantly increased by increased levels of acid water irrigation.

Geochemical adsorption and attenuation of contaminant migration by natural soils and rock can be an extremely powerful tool when the correct conditions exist. Geotechnical and geochemical expertise in these areas are available from:

CHEMICAL PRECIPITATION

ALUMINA-LIME-SODA PROCESS

The alumina-lime-soda process has been shown to be able to reduce high $SO_4^=$ concentrations to 250 ppm without difficulty through a two-stage process in which raw water is treated with aluminate and lime to pH 12.0-12.1 to precipitate calcium sulfoaluminate $2CaSO_4.Al_2O_3.3CaO.XH_2O$. Effluent from stage 1 is pH-adjusted by adding CO_2 to pH 7.

The principles, performance, and economics of the alumina-lime-soda process are described by NEGBEN, et al. (1976), and a copy of their paper was inserted in Chapter 24 on treatment of acid mine drainage.

More information and possibly updated economics may possibly be available from the authors:

PEREDERII (1979) in the U.S.S.R. published a description of a two-step process for the removal of Cu^{2+} and $SO_4^=$ from Cu mining wastewaters. In the first stage, the wastewaters were stirred at 700 rpm with a lime suspension at pH 12.35 (optimum condition). After settling, the clear liquor still contained 2,000 mg/l $SO_4^=$. In the second stage, the clear liquor was treated with Al(OH)5Cl and $Ca(OH)_2$ at pH 11.9 to precipitate $.3CaO.Al_2O_3.2CaSO_4.31H_2O$. The clarified wastewater was then discharged. The neutralization step gave a precipitate of $CaSO_4$ containing entrained Cu and Zn. The precipitate after drying could be used as a metallurgical flux.

A second U.S.S.R. application described by SAL'NIKOVA, et al. (1981) also involves the removal of calcium sulfate from wastewater by chemical precipitation. Ca and $SO_4^=$ concentrations of tailing leachate were reduced from 800 and 2,140 ppm to 180 and 300 ppm respectively by precipitation with aluminous cement to give insoluble non-toxic "ettringite" cement. The concentrations in minewater were also reduced from 310 and 3,470 ppm to 100 and 300 ppm respectively in a second application. The smaller amounts

of Cu, Fe, Zn, and Mg present in solution were also reduced. Not much more information was provided on this process other than the above from Chemical Abstracts.

The economics of the above chemical processes would likely depend on the cost of acquiring lime to reach high pH's in excess of 12 which, in the case of some solutions, would be expensive, and the cost of $Al(OH)_3$, Al(OH)5Cl, or aluminous cement. A further cost to take into account is that of safely disposing of the precipitated solids in a way that complies with the regulations. It is likely that these processes would cost no more than the treatment of water by R.O. which is estimated for large operations (5,000 m^3/d or more) to be around \$0.30-\$0.60/m^3 as a rule of thumb.

CHEMICAL REMOVAL OF SULFIDES

In straighforward metallurgical solutions, an obvious way to remove soluble sulfides from solution would be by adding a cation, e.g., Fe^{++} which forms an insoluble sulfide that also settles easily. In cyanidation pulps, when cyanide-soluble sulfides are present, it is common practice to add a soluble lead salt such as $Pb(NO_3)$ or $Pb(Ac)_2$ which then precipitates dissolved sulfides and also coats the surface of sulfide minerals thereby inhibiting the further dissolution of sulfide in the pulp solution. In so doing, sulfide dissolution is inhibited, and sulfide already in solution is precipitated. The alternative chemical method for removal of sulfide is through oxidation to a sulfate.

CHEMICAL REMOVAL OF THIOSALTS

No convenient way was encountered for chemical removal of thiosalts and thiosulfate. If thiosalts come in contact with cyanide solution, they usually consume cyanide and form thiocynate. Thiosalts can possibly be oxidized to sulfate by intense aeration at high pH, but this is an expensive, time consuming route.

ELECTROCHEMICAL

An unusual innovation was described by ANISIMOV, et al. (1978), another Soviet author, who treated mine pit water in a small rectangular plastic vessel equipped with a graphite anode and a metallic screen cathode separated by an asbestos diaphram. The wastewater contained Ca^{2+}, Mg^{2+}, K^+, Na^-, Cl^-, HCO_3^-, and SO_4^{2-}. The total salt concentration was about 14 g/l. In the reaction, Ca^{2+}, Mg^{2+} precipitated as hydroxides; K^+ and Na^+ formed KOH and NaOH; Cl^- yielded NaClO and $KClO^-$, H_2 evolved on the cathode, and clay particles were collected in the anodic compartment which was acidic. The cathodic compartment contained colloidal matter and gave an alkaline reaction. The processed water was used for flotation of coal sludges. Their paper does not describe what

happens to the sulfate. Presumably, it migrates to the acid anode compartment and probably remained as sulfate at a concentration that was higher than in the feedwater.

The description sounds as though it describes a bench-scale test. No commercial scale operations employing this process are known, and the economics are also not defined.

SISLER and SENFTLE (1977) described a biogeochemical neutralization of acid mine water in which biological processes are enhanced by applying an electric field. Not much is known about this still new branch of technology or its performance or economics.

Additional information on the nature of permeate, concentrate, and the recoveries possible by conventional R.O. systems from acid mine drainage may be contained in a report by the U.S. EPA written by WILMOTH (1973).

place at the natural pH of the ore. Only the zinc circuit is alkaline.

(2) Upgrading of concentrates at BMS is done by cleaning only, whereas SO_2 is used for Cu-Pb separation and to improve grade and recovery of Zn concentrate at BMS.

Rolia and Barbeau studied the contribution of sulphur dioxide to thiosalt generation in the flotation circuit at BMS (78). Their results indicated that bisulphite is formed initially upon addition of SO_2 to pulp slurries; the bisulphite then reacts with mineral particles, other thiosalts, and with air during flotation, resulting in more thiosalts.

LABORATORY STUDIES

To define the occurrence of thiosalts during beneficiation of sulphide ores, studies were conducted at CANMET from 1977 to 1980.

Rolia investigated the production of thiosalts during the grinding of pyritic ore from the BMS No. 12 mine (79). His findings were as follows:

(1) Thiosalts are produced during mixing of coarse ore (minus 10 mesh) with water, prior to any grinding. The amount generated increased directly with mixing time (Fig. 14).

(2) Thiosalts diminished by two-thirds during grinding with steel balls and tillets at the natural pH of the ore (pH 8), but increased during grinding with pebbles. This is probably due to either the scavenging ability of abraded iron for oxygen or the reduction of thiosalts by iron.

(3) There is an increase in the production of thiosalts with pH over the interval of 9.4 to 10.7, as indicated in Fig. 15.

(4) Less thiosalts are produced per unit weight of ore during grinding at higher pulp densities than at lower pulp densities (Fig. 16).

(5) A direct logarithmic relationship was found

Fig. 14 - Effect of mixing time on the production of thiosalts from coarse ore in a closed circuit; 70 rpm, 30% pulp density, pH 11.2

Fig. 15 - Effect of pH on thiosalt formation; closed circuit, 30 min, 60% pulp density, steel balls: X = thiosalts (Na_2CO_3-NaOH added); Δ = thiosalts (CaO added); o = sulphate

Fig. 16 - Effect of pulp density on thiosalt formation; closed circuit, 30 min, pH 10.7, steel balls

between the amount of thiosalts generated during grinding and the grinding time, as indicated in Fig. 17.

(6) Significant reduction of thiosalt generation (86%) occurred during grinding at pH 10.7 in a solution deaerated with nitrogen gas, indicating that production of thiosalts was repressed by exclusion of oxygen. Sulphite appeared as the principal sulphur species in the deaerated solution.

Investigations by the Noranda Research Centre indicated that some of the thiosalts in the ground pulp may originate from oxidized surfaces on the ore (80). Within the range of size distributions normally produced in grinding circuits, fineness of grind was found to have only a small effect on thiosalt generation during the grinding operation itself and subsequent flotation. The relative amounts of thiosalts originating from grinding and from flotation in a concentrator apparently depend largely on the pH in the two operations.

Other factors found to contribute to thiosalt formation were:

(1) Sulphide content of the ore; with five times the thiosalts generated in ores of 80-90% sulphides as with ores of 25-30% sulphides.

(2) Residence time during flotation; with the amount of thiosalts generated directly proportional to the residence time.

(3) Temperature; with thiosalt generation more than doubling from 25 to 40°C.

(4) Agitation rate in flotation; increased agitation promoted thiosalt formation.

Rolia and Barbeau studied the generation of thiosalts in a continuous process development mill at CANMET (Fig. 18) (81). The total amount of thiosalts generated was 959 g/t of ore; this compares with 1021 g/t of ore in the No. 3 flota-

Fig. 17 - Effect of grinding time on thiosalt formation; closed circuit, 60% pulp density, pH 10.7, steel balls

Fig. 18 - Continuous process development mill flowsheet at CANMET for the production of bulk concentrate

tion line at BMS before upgrading. A breakdown of thiosalt generation by operation was as follows:

Operation	% of Total
Grinding	17.6
Conditioning	37.0
Scavenging	45.5
Total	100.0

Steger investigated the effect of temperature, pH, particle size, and airflow on the formation and relative proportion of thiosalts in aqueous suspensions of samples of pyrrhotite, pyrite, chalcopyrite, galena, and sphalerite (82). An increase in the temperature or pH of a suspension resulted in an increase in sulphate and thiosalt formation. A decrease in the particle size of the mineral also resulted in increased sulphate and thiosalt formation. Changes in airflow had a marginal effect.

Rolia investigated generation of thiosalts during agitation of pulps on a variety of samples in a flotation cell (83). The results, presented in Fig. 19, indicated a clear correlation between the sulphur content and thiosalt production. No evident correlation was found between iron concentration and the amount of thiosalts generated.

THIOSALT TREATMENT METHODS

The CANMET thiosalt program evaluated a large number of thiosalt treatment alternatives. Most of these were limited duration bench-scale tests conducted inhouse. Two contracts were awarded - Noranda Research Centre evaluated pilot-scale biological removal of thiosalts using bacteria at Brunswick Mining and Smelting, Bathurst, N.B. and the University of Waterloo investigated catalyzed air oxidation of thiosalts using synthetic thiosalt solutions.

The following sections detail the studies which were conducted.

AIR OXIDATION

Solutions of thiosulphate and polythionates were aerated at pH 7 for 4 months under

Fig. 19 - Influence of sulphide content of various materials on the amount of thiosalt production after 5-h aeration

sterile laboratory conditions at the Noranda Research Centre (80). During this time, minimal changes in the thiosalt concentration were observed (<10%). Thus, it was concluded that air oxidation alone was not suitable for the destruction of thiosalts.

CATALYZED AIR OXIDATION

Process Description

A process for the removal of thiosalts by copper catalyzed air oxidation was tested by Rempel and O'Driscoll of the University of Waterloo (84). In the process, the effluent passes through a two-stage continuous aerated reactor containing slurries of synthetic resins combined with copper. In the first stage, the thiosulphate and trithionate are oxidized employing quaternized polyvinyl pyridine-Cu (QPVP-Cu) catalyst. In the second stage polyvinyl pyridine-Cu (PVP-Cu) is used for tetrathionate oxidation. The pH in both stages is controlled at 3 to 4.

The two types of catalyst used in the oxidation stages (PVP-Cu and QPVP-Cu) both deactivate slowly with time. The cause of deactivation of the PVP-Cu catalyst and to some extent of the QPVP-Cu catalyst appears to be the continuous leakage (soluble loss) of copper from the polymer complex. Deactivation of the catalyst on prolonged use is also believed to result from a considerable amount of thiosalt adsorption (i.e., $S_2O_3^{2-}$ and $S_4O_6^{2-}$) as well as SO_4^{2-} adsorption on the polymer matrix. Hence, periodic catalyst regeneration is required that involves pretreatment of the spent catalyst consecutively with HCl and NaOH to remove adsorbed thiosalt species followed by recomplexing with divalent copper. A simplified flowsheet of the process is illustrated in Fig. 20.

Fig. 20 - Simplified flowsheet for the copper-catalyzed air oxidation of thiosalts

Results of Tests

Tests of synthetic solutions containing 1680 mg/L S_2O_3 have been run at various temperatures and residence times using the catalyzed oxidation process. Based on these tests, optimum conditions appear to be pH 3 to 4, total residence time of 24 h (12 h per reactor), and temperatures from 35 to 40°C. To maintain an effluent quality of less than 100 mg/L thiosalts, desorption and regeneration of the PVP-Cu catalyst was required after 7 days of continuous operation. While desorption of the QPVP-Cu catalyst is also required after 7 days, regeneration is only necessary after 6 months. Typical results achieved during the tests are illustrated in Fig. 21.

Costs

Based on laboratory tests with synthetic solutions, Wong prepared preliminary capital and operating cost estimates for a plant capable of treating 1500 USGPM (5.67 m^3/min) mill tailings solution containing 5330 ppm $S_2O_3^{2-}$ (16 820 STPY or 15 255 MTPY) (85). The total fixed capital cost for this process in first quarter 1981 dollars is $17 495 000. The annual operating costs estimated for chemical reagents, catalysts and utilities only are $12 197 000 based on an assumed catalyst price of $2/lb with a life of one year. About 26% of the operating cost is for catalyst and 42% is for NaOH and HCl reagents. If the catalyst price is assumed to be $5/lb with

Fig. 21 - Continuous operating data for a two-stage copper-catalyzed reactor for thiosalt destruction: influent = 15 mM $S_2O_3^{2-}$ (1680 ppm); aeration rate = 1200 L/h; influent solution rate = 1.3 L/h (Day 1-4), 1.9 L/h (Day 5-7) and 1.5 L/h (Day 8-14). Reactor 1 (upper figure): QPVP-Cu (II) Catalyst (8.95% Cu (w/w), <75 μm); 2% (w/v) slurry; 12-L capacity; temp. 40°C. Reactor 2 (lower figure): Reilly-PVP-Cu (II) Catalyst (6.70% Cu (w/w) 50-500 μm); 2% (w/v) slurry; 12-L capcity; temp. 40°C (Day 1-5), 20°C (Day 6-7), 36°C (Day 8-14).

a life of one year, then the annual operating cost is $16 985 000 of which 47% is attributable to catalysts and 30% to NaOH and HCl reagents. On the basis of a catalyst life of 10 years, the estimated annual operating cost is from $9 324 000 to $9 803 000 for catalyst cost of $2 to $5/lb. However, the minimum possible operating cost is $8 253 000 if steam heating of the mill tailings solution is not required.

HYDROGEN PEROXIDE OXIDATION

Hydrogen peroxide is a strong oxidizing agent which is widely used industrially. Rolia investigated, in bench-scale tests, the oxidation of thiosalts utilizing hydrogen peroxide (86). He achieved complete oxidation of synthetic solutions (2.5 g/L thiosalts, as Na_2, S_2O_3 and $Na_2S_4O_6$) within 6 min using stoichiometric amounts of H_2O_2.

Reagent cost estimates (Dec. 1981), based on the treatment of 77 000 lb/d of thiosalts, amounted to $9.02 million per year. No capital cost estimates were provided.

CHLORINE OXIDATION

Rolia and Barbeau conducted laboratory tests to evaluate the kinetics and reagent requirements for the oxidation of synthetic solutions containing thiosulphate, tetrathionate, and trithionate using chlorine gas (87). They found that the oxidation rate depends directly on the rate of chlorine addition. The reaction required 2 moles chlorine for each mole of thiosalt sulphur. Reagent requirements for the destruction of 77 000 lb/d of thiosalts were estimated at $6 million per year (June 1979). No capital cost estimates were provided.

OZONE AND OTHER OXIDANTS

Environment Canada indicates that chemical oxidation of thiosalts may be achieved through the use of ozone, as well as chlorine sodium chlorate, sodium hypochlorite, and hydrogen peroxide (88). For ozonation, they propose the following reactions:

$$2\ S_2O_3^{2-} + 5\ O_3 + 2\ H_2O \rightarrow 4\ SO_4^{2-} + 3\ 1/2\ O_2 + 4\ H^+ \quad \text{Eq 86}$$

or

$$5\ S_2O_3^{2-} + 2\ O_3 + 7\ O_2 + 5\ H_2O \rightarrow 10\ SO_4^{2-} + 10\ H^+ \quad \text{Eq 87}$$

Their comparison of chemical treatment costs (Dec. 1975) is presented in Table 12.

SO_2-AIR OXIDATION

INCO has developed a process for the destruction of cyanide using SO_2-air oxidation. Preliminary tests carried out by INCO to evaluate thiosalt destruction using SO_2 and air were inconclusive due to a lack of analytical methods for thiosalt determination.

Rolia and Barbeau carried out tests to evaluate the effect of SO_2 and air on thiosalt solutions (87). They found minimal changes in thiosalt levels in tests of up to 48-h duration; in fact, in some tests, SO_2 combined with thiosulphate to produce more thiosalts. These tests were carried out without the addition of any catalysts (e.g., copper) which INCO utilizes for cyanide oxidation. In one of the tests, ferrous chloride was added, but it did not affect the results.

Oxidation of thiosalts by SO_2 and air and neutralizaton of acids thus produced probably occurs as follows:

(1) Formation of Caro's acid:

$$H_2O + SO_2 + O_2 \rightarrow H_2SO_5 \qquad \text{Eq 88}$$

(2) Oxidation of thiosulphate by Caro's acid:

$$S_2O_3^{2-} + H_2O + 4H_2SO_5 + 2H^+ \rightarrow 6H_2SO_4 \qquad \text{Eq 89}$$

(3) Neutralization of acid generated:

$$H_2SO_4 + Ca(OH)_2 \rightarrow CaSO_4 + 2H_2O \qquad \text{Eq 90}$$

Similar equations can be derived for the oxidation of other thiosalt species. Since SO_2 is converted to H_2SO_4, the neutralization requirements are greatly increased over other chemical oxidation methods.

Based on the above reactions, reagent costs (SO_2 and lime) for the destruction of 77 000

Table 12 - Comparison of chemical treatments for thiosalts (based on treating a 2 mgd stream of 1000 mg/L S_2O_3)

Chemical	Quantity required per lb S_2O_3	Estimated cost/lb $	Daily cost $	Estimated relative capital cost of facilities	Neutralization
Oxidants					
Ozone	1.06	0.16	3800	High	Yes
		0.125	2500	High	Yes
Chlorine	3.16	0.03	1900	Low	Yes

Lime	0.50	0.001	100	Low	-

lb/d of thiosalts can be estimated at $6.6 million per year (June 1982), assuming on-site generation of SO_2 gas from sulphur.

ALKALINE OXIDATION

Polythionates are unstable in alkaline solution, decomposing to elemental sulphur, thiosulphate and sulphite. Rolia studied the reaction kinetics for the decomposition of tetrathionate, trithionate and thiosulphate in alkaline solutions (89). He found that tetrathionate degraded rapidly to thiosulphate and trithionate at pH >10 and at 35°C. At higher temperatures (e.g., at 100°C), trithionate was found to decompose to thiosulphate and sulphate. The rate of hydrolysis of trithionate was not affected to any great extent from pH 5.5 to 12.

Thiosulphate was oxidized to sulphate by dissolved oxygen in alkaline solutions. The reaction was characterized by an induction period whose duration increases with increasing pH and decreases with rising temperature and pressure.

The oxidation of thiosalts in strongly alkaline media was studied by Rolia using slaked lime [$Ca(OH)_2$], sodium carbonate (Na_2CO_3), and sodium hydroxide (NaOH). Oxidation was always incomplete when [$Ca(OH)_2$] was used (90).

Complete oxidation was achieved using Na_2CO_3 but the oxidation rate was 80% of that obtained using NaOH. Other process variables were concentration of alkaline reagent, temperature, oxygen pressure, and thiosalt concentration. For an effluent solution containing 2500 mg/L thiosalts, two sets of preferred conditions were identified:

	1	2
Temperature, °C	150	100
Partial pressure of oxygen, kPa	2070	2070
Retention time, h	0.022	0.2
NaOH conc., g/L	1.92	1.92

Craigen estimated operating costs (June 1981) for the alkaline oxidation, using lime, of a 2000 U.S. gal/min stream containing 2000 mg/L S_2O_3 from $1 million to $2.4 million depending on the cost of steam (91). No capital cost estimates were provided. More recently, Weng calculated the annual operating cost at $5.2 million and the capital cost at $8.9 million (106) (Jan. 1982). Wong's cost were based on NaOH since lime lead to incomplete oxidation.

ULTRAVIOLET (UV) INDUCED OXIDATION

Haque evaluated UV oxidation of thiosalt solutions using a laboratory-scale reactor (UV source - 500 W Hanowa mercury vapour lamp) with air or oxygen bubbled through the solution (92). His results are presented in Table 13, and indicate:

(1) In the presence of gaseous oxygen, UV brought down the concentrations of thiosalt species to less than 2 mg/L.

(2) Results with air are similar to those achieved with oxygen.

No cost estimates, either operating or capital were provided.

REVERSE OSMOSIS (RO)

Reverse osmosis involves the forcing of water under pressure through a specially designed membrane which has the capability of allowing passage of pure water while rejecting impurities.

Sastri conducted laboratory RO tests using a static cell with a cellulose acetate membrane and tested both synthetic thiosalts and actual mill solutions (93). In initial experiments, he investigated separation of individual salts, and found that in each, maximum separation was achieved at 300 psig. Subsequently, he conducted tests with twelve different actual mill solutions at 300 psig. As indicated by the results in Table 14, effluent concentrations of less than 200 mg/L total thiosalt were achieved in most cases.

Dutrizac quotes capital cost estimates for an RO installation of 4000 U.S. gal/min at $5.4 million Can. and calculates operating costs from $0.63 to $1.02/1000 U.S. gal (94) (Dec. 1978). These costs do not include pretreatment for calcium removal or disposal of concentrated effluent.

lb/d of thiosalts can be estimated at $6.6 million per year (June 1982), assuming on-site generation of SO_2 gas from sulphur.

ALKALINE OXIDATION

Polythionates are unstable in alkaline solution, decomposing to elemental sulphur, thiosulphate and sulphite. Rolia studied the reaction kinetics for the decomposition of tetrathionate, trithionate and thiosulphate in alkaline solutions (89). He found that tetrathionate degraded rapidly to thiosulphate and trithionate at pH >10 and at 35°C. At higher temperatures (e.g., at 100°C), trithionate was found to decompose to thiosulphate and sulphate. The rate of hydrolysis of trithionate was not affected to any great extent from pH 5.5 to 12.

Thiosulphate was oxidized to sulphate by dissolved oxygen in alkaline solutions. The reaction was characterized by an induction period whose duration increases with increasing pH and decreases with rising temperature and pressure.

The oxidation of thiosalts in strongly alkaline media was studied by Rolia using slaked lime [$Ca(OH)_2$], sodium carbonate (Na_2CO_3), and sodium hydroxide (NaOH). Oxidation was always incomplete when [$Ca(OH)_2$] was used (90).

Complete oxidation was achieved using Na_2CO_3 but the oxidation rate was 80% of that obtained using NaOH. Other process variables were concentration of alkaline reagent, temperature, oxygen pressure, and thiosalt concentration. For an effluent solution containing 2500 mg/L thiosalts, two sets of preferred conditions were identified:

	1	2

ELECTRODIALYSIS

Electrodialysis involves removing inorganic ions from water by impressing an electrical potential across the water, resulting in the migration of cations and anions to the cathode and anode, respectively. By alternately placing anionic and cationic permeable membranes, a series of concentrating and diluting compartments results with the solution between one pair of membranes becoming depleted in solute while the adjacent solutions become solute enriched. The amount of electric current required for the demineralization is proportional to the number of ions removed from the diluting compartments.

No experiments were conducted to evaluate electrodialysis for treatment of thiosalt solutions. Dutrizac indicates that industry spokesmen believe that membranes used for sulphate removal would also be effective for thiosalts, and quotes operating costs from $0.50 to $1.00/1000 U.S. gal (Dec. 1978) (94). This does not include costs for removal of calcium or disposal of concentrate. Capital costs of a recently-built 3 million U.S. gal/day plant to treat brackish water correspond to $4 million Can. (Dec. 1978).

ELECTROOXIDATION

Bartels evaluated the treatment of thiosalts using electrooxidation (95). He outlined the main anodic reactions which are presented in Fig. 22. These can be divided into four general groups:

(1) Oxidation of thiosulphate in neutral-acid media.

(2) Oxidation of thiosulphate in alkaline media.

(3) Oxidation of polythionates in acid or alkaline media.

(4) Oxidation of sulphite and bisulphite in neutral, acid, or alkaline media.

Based on calculations for the direct oxidation of thiosalts on platinum, a thiosalt loading of 50 000 lb/d, and power costs of $0.0350/kWh, Bartels estimated power costs at $4.9 million per year. No capital cost estimates were provided. Among factors contributing to the high costs are:

(1) Complex multipath chemical and electrochemical reactions occurring during electrolytic oxidation.

(2) Buildup of dithionate which cannot be further oxidized anodically.

Fig. 22 - Anodic reactions occurring during electrooxidation of thiosalts

(3) Significant drop in current efficiencies below 500 mg/L thiosalt concentrations.

As of the date of the report (Sept. 1979), improved design of electrochemical reactors for thiosalt oxidation has not been proven. The carbon fibre anodes tested have evolved oxygen rather than oxidize the anions.

REDUCTION BY METALS

Based on observations of the disappearance of thiosalts following wet grinding of ore using steel balls, Rolia investigated reactions between metals and synthetic thiosalt solutions (96). His preliminary results, presented in Table 15, indicate that thiosalts could be completely destroyed in 24 h in the presence of nickel or iron; the fastest destruction occurring with iron.

Subsequently, he investigated the iron-thiosalt reactions more closely, concentrating on the effects of excess iron, temperature, and thiosalt concentration. Based on his experiments, he derived the rate expression governing the reaction. Qualitative tests indicated the evolution of H_2S gas and the generation of colloids consisting of Fe_2O_3, FeO and FeS.

Table 15 - Reduction of thiosalts by metals (Temp. = 80°C)

Metal/S mMole/mMole	Time h	$S_2O_3^{2-}$ mM	$S_4O_6^{2-}$ mM	$S_3O_6^{2-}$ mM

	4	6.1	6.3	1.0
	21	9.6	4.7	Nil
	47	11.7	1.8	Nil

Estimated operating costs for removing thiosalts by metallic iron was $7.1 million per year (January 1982) based on an effluent flow of 3000 U.S. gal/min, and a loading of 33 000 lb/d thiosalts. This does not include expenditures for the disposal of H_2S or FeS. The capital cost was estimated at $38.4 million, mainly attributable to using a ball mill as necessary contactor between iron sponge and the effluents (106).

ACTIVATED CARBON TREATMENT

Activated carbon is finding increased use in the treatment of municipal and industrial effluents. Removal of waste products from water by activated carbon involves the accumulation or concentration of substances at a surface or interface by adsorption, a process in which matter is extracted from one phase (i.e., liquid) and concentrated at the surface of another (i.e., solid carbon).

Rolia evaluated the removal of thiosulphate, tetrathionate and trithionate in synthetic solutions by activated charcoal (87). Essentially, no removal was achieved, despite varying pH from 6 to 12, temperature from 20 to 65°C, and residence time from 30 to 230 min.

Noranda Research tests of a number of adsorbents - activated carbon, bone charcoal, bituminous coal, peat, alumina, diatomaceous earth, clay - indicated that only activated carbon was able to retain significant quantities of thiosalts (80). Of the six commercial brands of activated carbon examined, Calgon Filtrasorb 200 appeared to be the best, having a loading capacity of 10 lb/100 lb of carbon in batch tests. Results of a column test indicated that a 5-ft deep bed having a total volume of 53 000 ft^3 (1 600 000 lb of carbon) would be required to treat 3000 Imp. gal/min of effluent containing 800 mg/L thiosalts at pH 2. Alkaline regeneration of the carbon bed was uneconomic. Alternatives such as biological regeneration may be possible but were not investigated because of the apparent high capital and operating costs of a carbon adsorption system.

BIOLOGICAL OXIDATION

Treatment of base-metal mine effluents containing thiosalts was first studied by Schmidt and Conn, who reported complete removal of 1000 mg/L thiosulphate in a bench-scale biological reactor at room temperature and a residence time of 18 h (97). The predominant bacterial species was Thiobacillus thiooxidans.

Laboratory studies by B.C. Research evaluated bench-scale Rotating Biological Contactors (RBC) and activated sludge units utilizing a synthetic feed (98). The unit achieved an oxidation rate of 70 mg/L/h, and the RBC achieved 1600 mg/L/h at room temperature and 120 L/h at 8.5°C.

Environment Canada carried out tests utilizing both bench- and pilot-scale RBC units (99). A flow diagram of the pilot-scale unit is presented in Fig. 23. Oxidation rates achieved using synthetic effluent and bench-scale units at 2°C were from 450 to 700 mg/L/h. At 30°C, rates as high as 1450 mg/L/h were achieved. Pilot-scale tests, carried out on site utilizing mill effluent from a metal mining operation in New Brunswick, achieved oxidation rates as high as 760 mg/L/h. Based on the results of the pilot-scale tests, Environment Canada provided cost data for an RBC facility treating 2.3 million Imp. gal/d of effluent containing 1250 mg/L thiosalts. Capital cost was estimated at $1.66 million and operating cost at $428 000 per year (May 1980). These costs do not include pre-treatment facilities such as primary clarification, flow equalization, or post-treatment facilities like lime neutralization, clarification, and possible supplementary chemical oxidation treatment, and the operating costs associated with such facilities. Also, the mechanical complexity of the system and the corrosive nature of the treated effluent (pH 2) would require close supervision of the process during operation and result in high maintenance costs. During the pilot tests, extensive corrosion problems were encountered, thus dependable continuing operation was difficult to maintain.

Meuller studied the oxidation of thiosulphate from the flotation waste waters of a base metal mine at Meggen, Germany, in bench- and pilot-scale packed towers (100). Packing materials tested included Raschig rings, quartz pebbles,

Fig. 23 - Flow diagram of the Environment Canada pilot-scale RBC

pilot-scale packed towers (100). Packing materials tested included Raschig rings, quartz pebbles, pyrite and native rock. The optimum thiosulphate oxidation rate was 470 mg/L/h in bench-scale tests and 200 mg/L/h in pilot-scale tests.

Noranda Research conducted bench-scale laboratory biological oxidation studies using a synthetic feed and on-site studies at Brunswick Mining and Smelting (BMS) using actual mill effluents (101). Two types of reactor were utilized: mixed aerated tanks (without packing) and extended surface packed reactors (using rock and foam packing). In addition, a rock packed column was evaluated.

Successful biological oxidation of thiosalt was achieved from 2.6 to 30°C, and the highest oxidation rates (about 1000 mg/L/h) were attained in the rock packed column and tank reactor. Lowering of the reaction temperature to 2.6°C resulted in an oxidation rate decrease of up to 50% over that achieved at room temperature. While the feed was generally pH 5 to 7, thiosalt oxidation resulted in the formation of sulphuric acid and subsequent pH depression. During optimal operation, the reactor effluent was pH 2.0 to 2.2.

It was noted that the packed reactors and columns were less sensitive to changes in feed composition and temperature than the mixed aerated tank. There was no evidence during the on-site tests of any toxic effect of components in the treated mill streams over a 5-month period. Colloidal sulphur, formed by acid decomposition of thiosulphate, was found to deposit on the packing material.

Dinardo carried out a literature review of thiosalt oxidation by thiobacilli species (102).

Silver and Dinardo studied the effects of temperature, initial pH, and concentration of ammonium, phosphate and heavy metals on the oxidation of thiosalts by an authentic strain of Thiobacillus thiooxidans (ATCC 8085) and by a mixed culture isolated from a base metal processing mill effluent pond (103). The optimum temperature was found to be 30°C and the optimum initial pH 3.75 for both cultures using thiosulphate and for the mixed culture using tetrathionate. T. thiooxidans ATCC 8085 did not oxidize tetrathionate. Highest rates of thiosalt destruction occurred at ammonium concentrations above 2 mg/L and in the presence of 1 mg/L of phosphate. Under optimal conditions, the pure culture oxidized thiosulphate at 55 mg/L/h; the mixed culture oxidized thiosulphate at 40 mg/L/h and tetrathionate at 50 mg/L/h.

Metal ions were found to cause inhibition in the kinetics of oxidation of thiosulphate by T. thiooxidans ATCC 8085, but only a slight additive effect was apparent in the presence of sev-

eral of the metal ions. The mixed culture of thiosalt oxidizing bacteria was less sensitive to heavy metal inhibition; the order of inhibition of thiosulphate oxidation was Cd < Zn < Pb < Ag < Cu and tetrathionate oxidation Zn < Cd < Pb < Ag < Cu.

Noranda Research is presently carrying out pilot tests of biological thiosalt oxidation using an aerated pond, a rock-packed aerated pond, and packed aerated columns. A flowsheet and layout schematic of the facilities are presented in Fig. 24 and 25. The study is partly funded by the federal Department of Supply and Services. Preliminary results indicate considerable variation, likely caused by the bacteria-inhibiting effect of lead in the feed. The maximum oxidation rate

Fig. 24 - Flowsheet of the Noranada Research thiosalt pilot plant

Fig. 25 - Schematic diagram of the Noranda Research thiosalt pilot-plant layout

achieved in the aerated columns was 160 mg/L/h and in the rock-packed aerated pond 70 mg/L/h. The process is also susceptible to fluctuations in the thiosalt concentration. Continuous operation was maintained during the winter months, with complete thiosalt removal being achieved at temperatures as low as 6°C.

Based on the results to date, it appears that a full scale system will require primary clarification, an auxiliary chemical oxidation system, lime neutralization, and secondary clarification facilities.

DISPOSAL TO THE SEA

Discharge of wastes to the sea is presently considered an acceptable disposal technique. In the U.S., the Environmental Protection Agency has designated more than 100 sites for ocean dumping of wastes (104). Generally, sea disposal methods involve careful control of discharge rates over sufficient discharge paths to ensure adequate dilution resulting in negligible changes in ambient seawater concentrations.

For mining operations located on or near a coastline and generating effluents containing significant levels of thiosalts, disposal of effluents to the sea may be a disposal alternative, if permitted by regulatory bodies. Francis carried out an assessment of a pipeline to carry effluents from a mine site near Bathurst, N.B., to Bathurst Harbour (105). A 75-cm O.D. pipeline fully powered with pumps and running a distance of 29 km including a 1.5 km long sea outfall would be required. A comparison of effluent thiosalt

and metal concentrations with background seawater levels is presented in Table 16. Francis estimated that the effluent would have to be diluted by at least 15 times to prevent significant changes in the seawater pH. The dilution factor would result in negligeable changes in the sulphate and metal levels of the seawater. A comparison with a similar size sewage pipeline near Pompano Beach, Florida, indicated dilution factors of 70 to 250:1 near the discharge point, and 1000 to 10 000:1 at a distance of 1.5 km from the discharge depending on wind and current velocity.

His estimates indicated capital costs of $5.5 million and operating costs of $50 000 per year (Jan. 1977).

COMPARISON OF COSTS

A summary of the methods reviewed above that indicated technical promise for the treatment of thiosalts is presented in Table 17. Where available, original costs presented by the authors are quoted. It should be emphasized that these costs in most cases are very preliminary estimates based on bench-scale test results. Also, in most cases, pre- and post-treatment facilities would be required to fully complete the teatment system to provide water which could be discharged to the water course.

Table 16 - Thiosalt effluent and seawater quality

	Effluent	Seawater
pH	5.5	not reported
SO_4, mg/L	1500	2800
Fe, mg/L	1.0	0.003 - 0.01
Cu, mg/L	0.03	0.003
Zn, mg/L	0.15	0.005 - 0.01
Pb, mg/L	0.1	< 0.001
Total thiosalt mg/L	2000	-

CHAPTER 52

THALLIUM Tl

Thallium occurs occasionally in ores, particularly in some disseminated gold ores which are often associated with high arsenic and sulfide levels. A classic example is the Mercur Gold Deposit near Toelle, Utah, now operated by GETTY MINES.

The area around the Getty Mercur Mine has been used extensively for sheep grazing, and no known incidences of thallium poisoning to livestock in the area have been identified, neither due to grazing on plants that have accumulated thallium, nor due to drinking local water.

Not very much is known about precisely how thallium is distributed in gold ore minerals at Mercur or other locations.

Employees of the Mercur Mine and of GETTY MINES LTD. have found that if it is present in the ore, thallium does leach in alkaline cyanide solutions at pH 10-10.5. Thallium also adsorbs onto activated carbon with gold to 400-600g Tl/ton carbon and occasionally to 1,000g Tl/ton carbon. Thallium does not seem to interfere or, in fact, to have any effect whatever on the leaching or recovery of gold from an ore. In some cases, it is possible that thallium is present in gold ores and that operators are not aware of it.

In the case of the Mercur Mine, the presence of thallium in the ore was known for a very long time. In fact, during very much earlier gold recovery operations at Mercur, operators in the refinery were fatally afflicted, and thallium was believed to have been the cause.

Thallium in the thallous sulfate form, for example, is highly toxic, it having been used as rat poison in years gone by. Thallium in most other forms is said to be much less toxic.

Thallium salts are also contact poisons and should not be allowed to come into contact with the skin.

At GETTY's Mercur Mine, thallium leaches with gold and adsorbs onto activated carbon in the leach circuit. Thallium is loaded onto the carbon to, typically, 400-600 g/t and sometimes 1,000 g Tl/t carbon. It appears that, by no means, all the thallium in the ore is leached, and that not all of it is adsorbed onto the activated carbon.

Loaded carbon is next rinsed and then washed in ambient 2-3% HNO_3 which removes about 80% of the thallium. The HNO_3 wash also removes arsenic and calcium from the carbon and some mercury (but not much), iron, and base metals.

Tl (ug/L) THALLIUM

pH of the acid wash solution is maintained at pH 2.

The acid rinse solution used to wash the loaded carbon is collected in a separate tank at pH 2. The concentration of thallium in this neutralization tank is around 1,000-1,200 mg/l at times, but more typically 800-900 mg/l. Next, NaOH is added to pH 9 or 10. As the pH is increased, Tl precipitates with the other metals. Then, a small amount of Na_2S is added to stabilize the hydrolized thallium precipitate and to make sure that any residual thallium is precipitated from solution with base metal sulfides. Caution is taken not to add Na_2S until after the solution has been neutralized to avoid the obvious dangers of H_2S generation.

Thallium is not quantitatively removed from the carbon by the cold HNO_3 rinse. Some stays adsorbed on the carbon but, to date, no problems have been identified that could be ascribed to the thallium in the circuit.

The sulfide-hydroxide precipitated metals are collected as a decanted sludge from the neutralization tank and bled into the tailings stream to be disseminated and lost in the lined tailings pond which is designed for zero discharge.

Not much is known about thallium distribution in rocks. It appears to occur reasonably often in disseminated gold ore deposits and may even be useful as a pathfinder element in mineral exploration for gold, although there is considerable debate on this.

The BUREAU OF MINES Bulletin 650 by Arthur Greenspoon is believed to contain a discussion to thallium distribution in ores. Mineral Facts and Problems 1970 mentions thallium in rocks and refers to levels of thallium up to 1,500 g/t at Mercur. It is believed that thallium may substitute for rubidium and potassium in sericite particles. Thallium, like rubidium, is a large, light ion.

The removal of thallium from gold metallurgical process solutions appears to be routine and easy as practiced at the GETTY Mercur Mine. It has been mentioned by WICKS and BREWER (1984).

This investigation included visits to several gold-uranium operations in South Africa and trip reports on DENISON MINES LTD. at Elliot Lake, KEY LAKE URANIUM LTD. in Saskatchewan, QUIVIRA MINING CO. at the Ambrosia Lake District of New Mexico, RØSSING URANIUM LIMITED, Swakopmund, South West Africa-Namibia, and the COTTER CORP.'s Schwartzwalder Mine, Colorado.

In this review it was also possible to draw from past RANDOL reports; for example, RANDOL (1978) and RANDOL (1979, 1980).

The five uranium operations described in Appendix I reflect a very wide diversity of geographic location, climate, and environmental as well as regulatory sensitivities. This diversity could be further extended by including examples of in situ leaching. Four additional trip reports on the KLOOF GOLD MINING CO., RM-3, VAAL REEFS, and ERGO describe gold-uranium recovery operations on the Witwatersrand from deep ore and from reclaimed tailings. Uranium recovery does not have to be the "hot" issue it has become in the U.S.A., Canada, and Australia.

A typical uranium leach extraction circuit is portrayed in a flow diagram for Jabiluka Uranium in Australia from LEVINS (1978). There are several variations on the theme to choose from.

Uranium decay gives rise to a chain of radioactive daughter products (illustrated below) that either accumulate in the ore or escape as a gas. The chain of elements, each decaying to the next, ends with Pb-210 which is radioactively stable. ITZKOVITCH and RITCEY (1979) provided an excellent summary review of radionuclides in uranium mill tailings; this review could likely be obtained by writing to:

GORDON M. RITCEY
CANMET - Energy, Mines Resources Canada
555 Booth Street
Ottawa, Ontario K1A 0G1
(613) 995-4124

When uranium ore is mined and milled, these daughter products may leach together with uranium in the extraction process, or they may be rendered water and/or acid soluble in the process, but they leach so slowly that these elements proceed to the tailings disposal area with the tailings pulp. Radionuclides may therefore occur in minewater, mill tailings, seepage from wasterock, and ore stockpiles and in effluents from the milling process.

Uranium mine wasterock and mill tailings, as well as minewater and mill effluents, can build up considerable concentrations of these daughter products as well as other soluble species, especially where process water and tailings decant solutions are recycled which is typically the case.

FIGURE 1. ACID LEACH FLOW DIAGRAM FOR ALLIGATOR RIVERS ORES

to prevent such radionuclides from entering the environment in water runoff or seepage from tailings and wasterock dump sites.

Radionuclides of concern are primarily uranium, thorium, lead-210, radium-226, and polonium-210. Frequently arsenic, molybdenum, and selenium, which are not radioactive, must also be taken into account in tailings. TAYLOR and ANTOMMARIA (1978) reviewed the natural geochemical attenuation of migration by these species from uranium tailings at a Wyoming site.

URANIUM - HEALTH EFFECTS

Apart from generating radioactive daughter products, uranium is in itself not particularly hazardous. Ingestion of high levels of uranium can result in liver damage.

ENVIRONMENTAL AND HEALTH IMPACTS OF RADIUM AND RADIONUCLIDES RELATED TO MINING AND MILLING ACTIVITIES

The U.S. NRC (1979) has outlined what is known about the health effects of radium and radionuclides released in uranium mining and milling as shown in the following excerpt.

The U.S. NRC Generic Environmental Impact Statement for Uranium Milling includes the following text on the hazards of radionuclides in uranium milling wastes:

> In ore bodies which have been undisturbed for many years there are equal amounts of radioactivity of each radionuclide. The common unit of quantity of activity is the curie (Ci), defined as 3.7×10^{10} disintegrations (or decays) per second (the SI unit is the becquerel, or Bq, equal to one disintegration per second). In ore containing 0.1% natural uranium (U_3O_8) there are 2.8×10^{-7} Ci of U-238 (10,000 disintegrations/second) per kilogram of ore. If nothing has occurred to remove any decay products, a condition known as secular equilibrium exists and there would also be present 2.8×10^{-7} Ci each of Th-234, Pa-234, U-234, Th-230, and Ra-226 per kg of ore. This does not imply that an equal weight of each isotope is present per unit weight of ore. The mass, or number of atoms, per curie is inversely proportional to the half-life.
>
> In Figure C.1, the disintegrations, or decays, by alpha particle emission are those which result in a decrease of 4 in mass number and 2 in atomic number (such as Po-210 to Pb-206) and are indicated by a line directed down and to the left at a 45° angle. These nuclides represent a negligible radiological hazard as long as they remain outside the body, but are serious health hazards once inside the body.
>
> It may be seen from the figure that radium-226 decays by alpha emission to radon-222. Radon, being an unreactive gas with a 3.82-day half-life, may escape from its immediate environment, whether that environment is an ore body, a tailings pile, or a bone in which radium has deposited. If a significant amount of radon escapes, then the decay chain will not be in a state of secular equilibrium from that point onward.
>
> Radon does escape into the atmosphere continually and outdoors is present in concentrations ranging from about 0.1 to 1 picocurie per liter of air (pCi/L). Radon is inhaled with each breath, but it is likely to be exhaled again without irradiating the respiratory tissues. When radon undergoes alpha decay, there follows within a short time a series of four more decays (two by alpha emission) before relatively stable Pb-210 (half-life of 21 years) is reached. The longest half-life among the intervening nuclides is only 27 minutes. The radon daughters are

not gases, but heavy metals, and rapidly become attached to available surfaces, usually to small airborne particles or aerosols. These aerosols, unlike radon gas, are easily deposited when breathed into the respiratory tract. Experience has shown that the bronchial epithelium (the lining of the bronchi) is an especially critical tissue, and that the total concentration of radon daughters, rather than the concentration of radon itself, is the parameter which best predicts the potential hazard. For this reason, in 1957 the U. S. Public Health Service introduced the concept of working level. One WL is any combination of short-lived radon daughters (meaning Po-218, Pb-214, Bi-214, and Po-214) in one liter of air that will result in the ultimate release of 1.3×10^5 MeV of alpha ray energy.[1] This amount of energy is the amount that will be released by the daughters in secular equilibrium with 100 pCi of radon. Unfortunately, radon and its daughters are almost never found in equilibrium, so a simple measurement of radon concentration will not reflect the potential inhalation dose.

When originally proposed, 1 WL was considered to be an acceptable maximum concentration for miners working a normal 40-hour week (170 hours per month). Exposures were described in "working-level months" (WLM). Thus 17 hours in an airborne concentration of 10 WL constitutes an exposure of 170 WL-hours or 1 WLM. The current EPA recommended maximum occupational exposure limit is 4 WLM per year, or 40 hours each week in a concentration of 1/3 WL.

Because the dose to lung tissue depends on respiratory parameters as well as on WL concentration and duration of exposure, it is not appropriate to determine continuous, nonoccupational exposure in WLM per year simply by multiplying WL by (24 × 365/170) to give about 52 WLM/year at a concentration of 1 WL. Instead, in this document it is assumed that a concentration of 1 WL yields 25 WLM/year for exposure that is continuous and nonoccupational. This reduction by about a factor of two reflects the difference in respiratory parameters appropriate for a worker engaged in physical activity and these parameters averaged over periods which include rest and other sedentary activity. To convert WLM of exposure to dose equivalent to the bronchial epithelium, it is necessary to make a number of assumptions about which there is not complete agreement among scientists. In this document a factor of 5 rem/WLM, based on the BEIR report, has been used in calculating doses and developing risk estimators (Appendix G).

Source: U.S. NRC (1979), Page C4

ONTARIO (1979) has set water quality objectives for radionuclides in receiving waters as follows:

Gross Beta Emitters, 100 pCi/l
Radium, 3 pCi/l

The rationale for these water quality objectives for radioactivity were established for protection of aquatic life and recreation.

It has been assumed by ONTARIO (1979) that if water is good enough for human consumption, then the radioactivity levels will not be harmful to other organisms. This assumption is supported by many reports in the literature, e.g.:

> "The doses that cause injury to plant and animal life are much higher than would be permitted under any circumstances in which human safety must be considered." (Environmental Radioactivity, 1973)

> "Compared with the experimental data available for warm-blooded animals, only a meagre amount of information is available on chronic dose-effect relationships for aquatic forms. The preponderance of available data indicates, however, that no effects are discernible on either individual aquatic organisms or on populations of organisms at dose rates as high as several rads/week." (EPA, 1973)

Both the levels listed above for gross beta emmiters and radium-226 are based on arbitrary considerations rather than firm evidence.

Fig. C.1. The Uranium-238 Decay Series.

3. RADON INHALATION

The concentration of Rn-222 at ground level depends on its rate of emanation from the ground and on the stability of the air near the ground. The emanation rate is extremely variable and is highly dependent on soil characteristics and meteorological conditions. The concentration of the parent Ra-226 and the grain structure and porosity both of the soil and of the cover material all affect the rate of radon emanation from soil. Barometric pressure has been reported to affect the radon flux from soil, a twofold increase in the radon emanation occurring when pressure drops by 1%.[10] Variation within 24-hour periods in Rn-222 concentration near the ground has been observed by many investigators.[11,12] Explanations for the concentration changes include effects of temperature, pressure, humidity, and air movement. However, the most significant cause for the fluctuations has been shown to be vertical exchange through eddy diffusion. Since radon concentration is highly variable, the dose from its daughter nuclides will also vary significantly. The dose values that are summarized here represent average values; the actual, short-term values can be expected to differ from the average.

The weather conditions at the model site are taken to be similar to those found in the western states. The concentration of Rn-222 in open air at ground level has been measured at different locations in the U.S. (Ref. 13 and Ref. 7, p. 79), including a site in New Mexico for which the average concentration over a six-year period was 240 pCi/m^3. Other studies (Ref. 18, 19) have measured outdoor Rn-222 concentrations in western areas ranging from about 60 pCi/m^3 to over 2000 pCi/m^3. A value of 240 pCi/m^3 is thought to be a conservative average value for outdoor Rn-222 concentrations in western regions. The concentration of Rn-222 in buildings is generally higher than in the open, depending on the Ra-226 content of the construction materials and the degree of ventilation of the building. Indoor concentrations as low as 5 pCi/m^3 (Ref. 14) and as high as 4800 pCi/m^3 (Ref. 7, p. 82) have been reported. George and Breslin have measured Rn-222 concentrations in homes in the New Jersey-New York area (Ref. 20). They have reported a geometric mean of the Rn-222 concentrations on the first floor of houses of about 830 pCi/m^3. The geometric mean for outdoor concentrations in the New Jersey-New York area is about 180 pCi/m^3. An indoor concentration of about 900 pCi/m^3 for western regions can be derived from George and Breslin's work by substituting the conservative outdoor Rn-222 concentrations for western regions (240 pCi/m^3) for the New Jersey-New York outdoor concentrations (180 pCi/m^3).

The average value (900 pCi/m^3) would result in a bronchial dose of 560 mrem/year (based on the dose conversion factor of 0.625 mrem/yr per pCi of Rn/m^3, which is used throughout this document). American Indians living in the region generally inhabit poorly ventilated huts with mud-lined walls. Houses made with sun-dried, unburnt clay have been found to have an indoor Rn-222 concentration of 1760 pCi/m^3 (Ref. 15). Since the huts are made of similar material, a dose of about 1100 mrem/year to the bronchial epithelium would result.

The air in a trailer-home could be expected to have about the same concentration as the outside air. Thus, an individual living in a trailer would breathe air with a concentration of 240 pCi/m^3 and would receive a dose to brochial epithelium of approximately 150 mrem/year.

4. TECHNOLOGICALLY ENHANCED RADIATION

The reader is referred to References 16 and 17 for a discussion of technologically enhanced radiation. The study described in Reference 17, which specifically addresses technologically enhanced sources of radon, was funded by NRC in support of developing regulations for the disposal of mill tailings.

APPENDIX K-2. COSTS OF ALTERNATIVE SPECIAL TAILINGS CONTROL PROCESSES

Costs of a number of special tailings control processes (described in Sec. 8.2) are considered in this appendix. Some of these processes are simple, involving as few as one piece of machinery, while others involve complex networks of machines and pipes. Also, the design and costs depend rather specifically on the exact purpose of the installation. Most of the processes described below are used only in tailings disposal Alternatives 7 and 8. The costs quoted are tailored to that use; however, the values cited should give general ideas of costs for other installations. Process numbers on the flow sheets in Appendix K-4 (Figs. K-4.1, K-4.3, K-4.4, and K-4.5) are keyed to the numbers given in the pertinent discussion in this section. Detailed descriptions and engineering cost evaluations of most of the mechanical processes are contained in Reference 1.

1. SANDS-SLIMES SEPARATION

Sands would be separated from the slimes in two cyclone separators costing (installed, 1978) $15,000.

2. DEWATERING FILTER BED

For open-air drying of slimes (by use of a dewatering filter bed), it is assumed that an area sufficient to hold three years' production of slimes in a one-meter-deep layer (about 40 ha) would be necessary. After two years of drying, the slimes would be recovered for processing or disposal and the vacated portion of bed prepared for reuse. The tailings drying area would be lined with Hypalon and protected by an earth or sand layer. Small berms would be needed to enclose the entire area and to form cells to separate fresh from dried tailings. Also, grading and drainage would have to be provided. Preparation costs are estimated at $2500/ha and installation and covering of the Hypalon liner at $40,000/ha.[2-5] Restoration costs at the end of operations are also expected to be about $2500/ha. Costs for total tailings are estimated as twice those for slimes (i.e., 80-ha bed).

3. FOSSIL-FUELED EVAPORATORS

The capital costs of evaporators and associated equipment with an evaporation capacity of 4.6×10^5 m^3 of water per year are estimated as $1.45 million (1978 costs).[1] With a 70% thermal efficiency, 90,000 MT of coal per year would be required, at a cost of $2.55 million.

4. EVAPORATION POND

The evaporation pond is assumed to have an area of 40 ha and to require a 5-m-high dam; the bottom would be lined with Hypalon. The costs are estimated as $70,000 for site preparation, $50,000 for the dam, and $1.6 million for the liner. After 15 years of operation, about 30 cm of soluble salts would be deposited on the pond bottom. It is postulated that these solids would be collected in a 6-ha area, then covered with a second Hypalon membrane and 2 m of earth. The cost to collect and cover these salts, then restore the entire 40-ha evaporation pond area is estimated to be $600,000. The total cost is thus $2,300,000.

5. HORIZONTAL VACUUM BELT FILTER

A horizontal vacuum belt filter probably could be used to filter and wash whole tailings or sands; however, the filtration of slimes alone probably would not be feasible. For the whole tailings from the model mill it is estimated that a filter of 64 m^2 area,[6] at a cost of $810,000,[7] would be required. For separated sands an 8 m^2 filter costing $210,000 would be used.[6,7]

6. LIME NEUTRALIZATION

The slimes and liquid would be neutralized with lime. Details of the equipment and cost estimates are given in Reference 1. The costs are estimated to be $670,000, including lime-handling and

Excerpt from: Generic Environmental Impact Statement on Uranium Milling, U.S. Nuclear Regulatory Agency, April 1979, Draft.

-mixing equipment, instrumentation, and auxiliary equipment. Each day 22 MT of lime would be used at a cost of $27/MT delivered.[1]

7. SLIMES FILTRATION (disc filter)

The neutralized slime slurry would be treated in thickeners and filtered in vacuum disc filters (200 m^2) at a total cost of $1.15 million (1978, installed).[1]

8. CEMENT FIXATION

Costs of equipment for cement fixation are also described in Reference 1. Materials-handling and mixing equipment, instrumentation, and associated apparatus would be required, at an estimated cost of $1.20 million (1978). To provide a sufficient degree of resistance to leaching by groundwater, a mixture of one part cement to five parts slimes (dry basis) would be required, or 110 MT of cement per day at $50/MT.

9. ASPHALT FIXATION

Costs of equipment for asphalt fixation are described in Reference 1. The capital costs would include materials-handling and mixing equipment, wiped film evaporators which combine mixing of asphalt with further drying of tailings, instrumentation, and associated equipment, for a total cost of $4.4 million (1978). About 750 kg of asphalt would be required per metric ton of dry slurry (420 MT/day) at a cost of $22/MT of asphalt. The equivalent of 50 MT of coal per day (cost, about $1,400) would be required for evaporation of water from the asphalt mixture carried out in the wiped film evaporator.

10. BARIUM CHLORIDE TREATMENT

The costs of barium chloride ($BaCl_2$) treatment are largely those of the material plus the costs of a series of lined settling ponds. The amount of $BaCl_2$ added can range from 0.03 to 0.1 g/L of tailings solution,[8] and about 1200 MT of tailings solution (Ch. 5) must be treated. The cost of $BaCl_2$, including transportation, is about $385/MT (1978) for a materials cost of $14 to $38 per day. A total load requirement for 40 ha in three or four plastic-lined settling ponds would cost about $2 million. Restoration would add about $100,000 more to the costs.

11. ION EXCHANGE

Although not considered in the alternative tailings disposal programs, the removal of radium from tailings solution using ion exchange is a potentially viable process.[9] To remove about 99.5% of the radium from the tailings solution, about 1200 kg/day of barite (natural barium sulfate) would be required as a disposable ion-exchange bed. The cost would be about $200/day ($76,000/year). The used barite would be relatively inert and could be disposed of in the tailings pile. Lime neutralization and filtration would be required pretreatment of the tailings solution.

12. NITRIC ACID MILL

The capital and operating costs of a nitric acid mill may be estimated by using the costs given in Reference 10 for a sulfuric acid mill and comparative costs for the two types of mills given in Reference 1. For equipment, the costs are about $7.1 million for the sulfuric acid mill and $37.7 million for the nitric acid mill. Additional capital costs include those for building and site development, utilities and connections, engineering costs, and contingencies. These items add $16.8 million to the costs of the sulfuric acid mill. The non-equipment items for the nitric acid mill probably would not be proportional in cost since a substantial fraction of the extra equipment costs are for similar items in stainless steel rather than wood or mild steel; furthermore, a larger plant area would be required for the equipment of the nitric acid plant. It therefore is assumed that the non-equipment costs for the nitric acid plant are about double those of the sulfuric acid plant, or about $35 million.

Operating costs for the sulfuric acid mill (including reagents) are given as $8.40 to $9.84 per ton of ore processed and for the model mill are assumed to be $9.00 per ton.[10] Total operating costs of $12.50 per ton are then obtained for the nitric acid mill. Annual operating costs for the model mill would be $5.6 million if sulfuric acid were used and $7.7 million for the nitric acid version. Lifetime (15 years) costs are $108 million and $189 million for sulfuric and nitric acid mills, respectively. Tailings disposal costs for the nitric acid mill are discussed in Section 10 of Appendix K-4. The costs of the two types of mills are summarized in Table K-2.1.

Table K-2.1. Costs of Nitric and Sulfuric Acid Mills (in millions of dollars)

	Nitric Mill	Sulfuric Mill
Equipment (including piping and instrumentation)	37.7	7.1
Construction and building	35	16.8
Lifetime (15-year) operating costs	116	84
TOTAL (rounded)	189	108

LEVINS (1979) reviewed the environmental impact of uranium mining and milling in Australia. Australia has almost 20% of the western world's low-cost uranium reserves located mostly in the Alligator River Region of the Northern Territory. This area, subject to very dry seasons and monsoonal downpours of short duration, presents special problems in water management. More information can be obtained from:

AUSTRALIAN ATOMIC ENERGY COMMISSION
Research Establishment, Lucas Heights
NSW 2232, Australia
Desmond M. Levins

LEVINS (1979) points out that Alligator River ores contain very little natural thorium, but about 60% of the thorium-230 in the ore is dissolved during processing according to LEVINS, et al. (1978).

Only 0.1-0.3% of the radium 226 is released into solution during leaching.

Apart from acid raffinate, the only other process waste of importance is the ammonium sulfate effluent arising from yellowcake precipitation and solvent stripping. It is normally discharged with the tailings although, in some cases, it is first treated to recover ammonium for recycle as has also been practiced at KEY LAKE MINING in Canada.

REGULATORY LIMITS; URANIUM, RADIUM, AND RADIONUCLIDES

South Africa is one of the world's largest uranium-producing countries. Unlike other major producers, all of its uranium production is concentrated in one area, the Witwatersrand, where uranium is produced as a by-product of gold. It is in a way remarkable that there are no regulatory limits for uranium or radium and its daughter products in tailings and effluents from these operations. Despite careful investigations, no evidence of adverse health effects on miners, mill operators, or the public has been identified related to possible radioactive contaminants. In this area, where the city of Johannesburg and the major extensions to this metropolitan region have grown as gold mines opened up to the west and east, and later in the far west rand and Orange Free State goldfields, the urban population is often settled in very close proximity to huge mill tailing dumps and even on reclaimed mine, mill, and tailings sites.

This raises the question as to whether the attention radionuclides in effluents from uranium mines and recovery operations in other parts of the world deserve the, at times, paranoid attention that they have attracted in the recent past.

It is beyond the scope of this investigation to pass judgement on this question, and the health effects and environmental impact or non-impact of radionuclides are not reviewed here beyond a few cursory observations. It is, however, fair to note that the uranium

grade in Witwatersrand ores at around 0.1-0.2 Kg/t is much lower than in most other primary uranium mining districts.

The uranium supply is now becoming increasingly met by newer mines that treat very high-grade and low-cost ores such as in Saskatchawan around the Athabascar Basin, the Northern Territories of Australia, etc. where radionuclide concentrations are higher by an order of magnitude or two.

As far as a mining company is concerned, it matters not whether a regulation is logical or not--if one wants to operate, the regulation must be met (or changed).

One of the great problems that was faced by companies in the U.S.A. (and possibly Australia, too) was not so much the regulations, but the lack of them. During the uranium boom of the late 1970's, numerous applications were filed with the NRC for permits to open new uranium mines and mills. The regulations were in a formative stage of development and, as such, permits were held up for an inordinate length of time while the NRC went about its task of reviewing, evaluating, and creating new regulations. Eventually the uranium boom had come and gone by the time the NRC was ready to issue permits and firm up regulations and effluent limits.

In the U.S.A., regulation of uranium mines and mills at the federal level is the responsibility of the U.S. Nuclear Regulatory Commission.

U.S. NUCLEAR REGULATORY COMMISSION
Washington, DC 20555
(202) 492-7000
Ross Scarano

However, the regulation of uranium mining operations is increasingly left to the individual states provided they contract with the U.S. NRC to promulgate and enforce state regulations that are at least as stringent as the federal NRC regulations. It appears that the federal government is intent on delegating this responsibility as much as possible to the state authorities. New Mexico, Colorado, and Wyoming, where most operating underground uranium mines are located, are "agreement states," which means that they have entered this contract with the NRC. Texas, where much of the in situ leaching of uranium is carried out, is also an agreement state. Appropriate state authorities charged with regulation of the uranium industry are:

Anyone contemplating becoming a uranium producer in the U.S.A. will find that just about every aspect of his operation is subject to regulatory control and scrutiny and also exhaustive pre-permitting baseline study requirements and post-startup environmental monitoring and reporting needs. These are described by U.S. NRC (1979) and in summary by MARTIN (1978) who described the objectives and direction of the Nuclear Regulatory Commission uranium mill licensing program.

In in-situ leaching of uranium, the extent of licensing requirements will depend on whether the operation will produce uranium in slurry form or whether a yellowcake drying operation will be installed, in which case, careful air sampling requirements must be met.

The site of at least one former uranium recovery operation, namely the old COTTER CORPORATION millsite at Canon City, Colorado, has been designated as a "Superfund" site for cleanup under CERCLA regulations. It is likely that the owners of this site and others will have to defend themselves in litigation aimed at covering the cost of repairing environmental damage at this and several other uranium processing sites across the U.S.A.

REGULATORY LIMITS FOR Ra AND URANIUM MILL EFFLUENTS

Operaton	Date	State	Ra (p Ci/l)	U (ppm)
Key Lake Uranium	1984	Saskatchewan (Mo. Ave.)	10	0.50
Saskatchewan		(Max. Grab)	30	-
Quivira Mining	1984	Mine	3	1
New Mexico		Mill	Zero Discharge	

REGULATORY LIMITS FOR Ra AND URANIUM MILL EFFLUENTS (Continued)

Operaton	Date	State	Ra (p Ci/l)	U (ppm)
Denison Mines Ltd. Ontario	1984	Elliot Lake, Ontario (Mo. Ave.)	5.0	-
Cotter Corp. Minewater Colorado	1984	Colorado	5	0.06
Rössing Uranium Ltd. SWA-Namibia	1984	Mine/Mill	Zero Discharge	

It must be remembered that often acid and alkaline leach liquors and pulps in uranium extraction will contain several other metals in solution and that they are also likely to be regulated in effluents. Processes designed to remove, say radionuclides, should therefore take into account what other contaminants are present in a given operation which may simultaneously be removed.

LAKSHMANAN and ASHBROOK (1979) referred to a Canadian federal maximum permissible concentration (MPC) of 10 p Ci/l (0.37 Bq/l soluble Ra-226).

The AECB (1978) Joint Government-Industry Program in Canada suggested that 10 p Ci/l total Ra-226 be considered as an effluent guideline.

The province of Saskatchewan has a receiving water quality objective of 3 p Ci/l of total Ra-226.

LEVINS (1978) and HART (1974) showed the following water quality standards and derived aquatic standards in Australia:

AUSTRALIAN WATER QUALITY STANDARDS

	Drinking Water Standards		Derived Aquatic Standards		
	Max. Permissable (mg/l)	Max. Desirable (mg/l)	LC 50 (mg/l)	Application Factor	Standard (mg/l)
Cu	1.5	0.05	0.04	0.05	0.002
Pb	0.1	N/A	0.18	0.01	0.002
U	10	N/A	2.5	0.01	0.025
Zn	15	5	0.14	0.005	0.001
Mn	0.5	0.05	10	0.01	0.1

It is of interest to note that in Australia, water quality standards have been selected which are five thousandths to one twentieth of the LC 50 concentration for various metals.

According to RYAN and LEVINS (1979), in Australia uranium tailings cannot be disposed of in an unrestricted manner unless the radionuclide content is reduced to near background levels, say less than 0.2 Bq/g. To meet this criteria, over 99% of the uranium radium, and thorium must be removed from the average uranium ores mined in Australia. Even the impractical sodium chloride process to leach radium described in their paper results in 80-90% radium removal and a residual radium activity of 2 to 11 Bq/g which is still an order of magnitude above levels for unrestricted disposal.

TREATMENT OF URANIUM MINE/MILL EFFLUENTS

In mine/mill effluent and water management, several factors need to be taken into account:

- The effect on water quality when solutions are recycled. What effect does recycling have on the salt load, individual contaminants, and on metallurgical recoveries, corrosion, and scaling phenomena.

- If it is essential to discharge an effluent because of water and/or salt balance characteristics, it may be necessary to treat this water.

- The impact of seepage and runoff from the working area, ore, and wasterock stockpiles and mill tailings on groundwater and surface water quality must be determined.

- In dry areas where water is in short supply, water consumption must be minimized. This can have an effect on water quality. For example, Rössing consumes 0.39 m^3/t fresh water whereas QUIVIRA MINING in New Mexico consumes several times that amount.

- If water treatment is contemplated to remove, say, radium from effluents, it would be just as well to consider a process that would remove the other unwanted contaminants (radioactive and non-radioactive) at the same time.

- In removing uranium, radium, and other radionuclides from effluents, a suitable means of disposal of the precipitate sludges or concentrated solutions generated should be devised.

FIGURE 4. CONCENTRATION OF ^{226}Ra IN NEUTRALISED TAILINGS-RAFFINATE SLURRIES

FIGURE 5. AGEING OF KOONGARRA TAILINGS - RAFFINATE SLURRY AFTER LIME-TREATMENT TO pH 8.0

According to LEVINS (1979), the behavior of radium during lime treatment is complex. According to his Figure 4 shown on the following page, during neutralization of Alligator River tailings-raffinate slurries, the concentration of radium-226 actually rises, reaching a maximum at pH 6. This effect is not completely understood but is believed to be related to the decrease in sulfate concentration as a result of precipitation of $CaSO_4$ (LEVINS, et al., 1978). This could lead to dissolution of radium sulfate held on the tailings in accordance with the common ion effect. Above pH 6, radium is removed from solution by adsorption, co-precipitation, and hydrolysis. His Figure 5 shows that further radium is removed from solution if the neutralized slurry is allowed to age at constant pH for several days. The concentration of sulfate in solution also decreases during this period. The net effect of all these factors is that the concentration of radium-226 in aged waste treated with lime to pH 8 is approximately the same as in acidic waste.

Several alternative approaches to radium and radionuclide removal from uranium mill tailings have been considered. Of these, only one has been applied in industry for both the removal of Ra from liquid mill effluents, minewater, and for precipitation of Ra for disposal in tailings. This process consists of the addition of $BaCl_2$ and settling. There are several variations on this theme including:

- pH adjustment to around 6-7 before $BaCl_2$ addition.
- Aging after $BaCl_2$ addition.
- $BaCl_2$ addition in stages.
- Addition of coagulants and flocculants to aid $BaRaSO_4$ settling, e.g., $FeCl_3$, $Fe_2(SO_4)_3$, and alum.

RADIUM PRECIPITATION WITH $BaCl_2$

At the request of the Abatement and Compliance Branch of the Environmental Protection Service, a bench-scale test project was undertaken at the Wastewater Technology Center at Burlington, Ontario, during 1976-1977 and is described by WILKINSON and COHEN (1977). The objectives of this project were to provide a better understanding of current physical-chemical methods of removing Ra-226 from uranium-mine effluents and to develop technology that would enable the uranium mining industry to comply with existing and anticipated effluent limits. The WTC bench-scale studies showed that total Ra-226 levels of less than 10 p Ci/l could be achieved using barium chloride as the precipitant and either ferric chloride or alum as coagulant.

MOFFETT and VIVYURKA (1979) in an independent study at the RIO ALGOM LTD. facilities investigated the effect of $BaCl_2$, $FeCl_3$, and superfloc additions on the rate of precipitation and settling of Ra-226 as a function of time from effluent solutions using settling columns 10 feet (305cm) tall and 24.8 cm in diameter. The total radium content, even after 72-hours settling time, did not meet the level of 10 p Ci/l.

LAKSHMANAN and ASHBROOK (1979) described testwork on $Ba(Ra)SO_4$ settling on Marie Lake overflow at the Beaverlodge operations of ELDORADO NUCLEAR LTD. Settling columns 305 cm high and 24.8 cm internal diameter were used. The test included investigations of the effects of temperature, mixing time, and addition of barium chloride, ferric chloride, and ferric sulfate on the precipitation and settling of $Ba(Ra)SO_4$.

These tests concluded that:

1) Total Ra-226 at less than 10 p Ci/l can be obtained under summer conditions after 72-hour settling when 15 ppm $BaCl_2$ and 25 ppm $Fe_2(SO_4)_3$ are used as precipitant and flocculant respectively.

2) Total Ra-226 at less than 10 p Ci/l after 72-hour settling could not be achieved in tests carried out at a simulated winter temperature of 4°C'.

The Beaverlodge tailings were generated using an alkaline uranium leach process whereas the Elliot Lake tailings tested by MOFFETT and VIVYURKA (1979) were acid leached uranium tailings.

LAKSHMANAN and ASHBROOK (1979) found that suspended solids containing finely divided $BaRaSO_4$ and fine tailings were responsible for the residual radium-226 in the treated effluent.

The sludges produced in these tests where ferric sulfate and $BaCl_2$ were used varied between 408-754 p Ci/g, whereas the normal Dorrclone overflow at Beaverlodge contains Ra-226 at 705-805 p Ci/g in suspended solids.

MOFFETT, et al. (1979) reported on a joint industry-government program to develop a more effective method of radium removal including development of physical/chemical treatment systems as an alternative to settling ponds. Target Ra-226 activities for treated tailings basin effluents were set at 10 p Ci/l total and 3 p Ci/l dissolved Ra-226. The program led to the selection of two physical-chemical processes which met the radium-226 target activities. The pilot plant was located at the Quirke Mine of RIO ALGOM LTD. at Elliot Lake, Ontario. The trailer-mounted plant was positioned below the main dam of the Quirke tailings basin and had a nominal capacity of 5 lgpm. The processes investigated included co-precipitation of $(Ba,Ra)SO_4$ with subsequent solid-liquid separation by flocculation/clarification or granular media filtration.

The mean Quirke tailings basin overflow prior to treatment by $BaCl_2$ addition had the following composition in 1977/1978 according to MOFFETT, et al. (1979).

QUIRKE TAILINGS BASIN OVERFLOW

Ra-226,	Total p Ci/l	820
	Dissolved p Ci/l	800
pH		9
$SO_4^{=}$	mg/l	1,330
Suspended Solids		2
TDS		2,480
NH_3,	(mg/l NH_3-N)	23
NO_3,	(mg/l No_3-N)	77
Calcium,	(mg/l)	480

Three continuously stirred tank reactors with a total residence time of 115 minutes were used for the $BaCl_2$ addition step to provide adequate contact time for continuous $BaCl_2$ addition.

Over a 12-month monitoring period, the tests showed that performance of the precipitation system varied and that special reactor designs would be needed to maintain acceptable performance under all conditions. The reactors can produce a dissolved Ra-226 activity of 3 p Ci/l, although some dissolved radium measurements exceeded 10 p Ci/l. MOFFETT, et al. (1979) concluded that the causes of the variability in the $BaCl_2$ precipitation of Ra-226 needed further investigation.

Laboratory and bench-scale tests showed that the settling rate of barium-radium sulfate could be markedly enhanced by the addition of ferric chloride as a coagulant. Tests by WILKINSON and COHEN (1977) established an optimum $FeCl_3$ dose as 4 mg/l (as Fe) although the settling rates achieved by coagulation were very slow compared with conventional clarifier hydraulic loadings. A hydraulic loading of 150 lgpd/ft^2 was selected for the pilot plant.

$FeCl_3$ (at 4 mg/l Fe) was added in the rapid mix step to the overflow from the precipitation reactors and subsequently flocculated in series connected flocculators with 80 minutes residence time. This achieved an overflow with 48 p Ci/l Ra-226 which formed a baseline for their further testwork.

Further improvements were achieved when precipitate sludges were recycled and an additional polymer was added after $FeCl_3$ addition in two flocculators in series. In this case at 150 lgpd/ft^2 hydraulic loading, the Ra-226 activity was reduced from 48 p Ci/l to 22 p Ci/l when sludge recycle was used. When an inclined plate clarifier was installed with a hydraulic loading of 600 lgpd/ft^2, the "once through" effluent had a total radium activity of 32 p Ci/l. With sludge recycle, this dropped to 14 p Ci/l.

A very significant reduction in the radium activity was achieved by increasing the sludge recycle rate to the flocculator until a suspended solids level in the flocculator reached 3,000 mg/l. This improved the settling rate of the iron/barium precipitate to give a reduction to 8 p Ci/l total Ra-226.

Ultimate improvements showed that at 10,000 lgpd/ft^2 and below it was possible to produce an acceptable effluent with 8 p Ci/l total and 3 p Ci/l dissolved Ra-226 in overflow from the plate clarifier while maintaining 3,000 mg/l solids in the flocculator and a sludge age of about four weeks. The schematic of this flocculation/clarification process is given in their Figure 5 which also notes an addition of an anionic polymer (0.4 mg/l AQUAFLOC 465) between the two flocculators.

MOFFETT, et al. (1979) also tested granular media filtration as an alternative to flocculation/clarification for the removal of the precipitated $BaRaSO_4$ which was investigated both with and without filter aids. Small doses of ferric chloride were found to act as an effective filter aid. If too much ferric chloride was added, however, the surface of the filter quickly clogged.

The MOFFETT, et al. (1979) paper very adequately describes a variety of experiments which ultimately led to filtration rates of 8 lgpm/ft^2 for 10-hour runs and 22 hours at 6 lgpm/ft^2 using 0.01 mg/l PERCOL 727 additions for one hour in every eight-hour cycle.

Dual media filters extended the filtration runs further for polymer-aided runs.

The ultimate configuration of the plate clarifier aided process with sludge recycle and the dual media filtration pilot plant arrangements are shown in their Figures 5 and 9 below.

These tests undoubtably formed the basis for the effective radium removal plant described in the KEY LAKE trip report in Appendix I.

ITZKOVITCH and RITCEY (1979) carried out a paper study on techniques for the removal of the radionuclides radium-226, lead-210, and thorium-230 from sulfate, carbonate, nitrate, and chloride streams produced in uranium ore processing. Detailed in a final report available from CANMET is the origin and control of radionuclide contamination of mill effluent streams from conventional and non-conventional milling of uranium ores. The basic chemistry of radionuclides of concern as it relates to potential alternatives along with published cost data are presented. Their paper summarizes the conclusions arrived at from the critical assessment of the published literature. ITZKOVITCH and RITCEY (1979)'s summary and the complete report are available from:

Head, Solution Purification Section

These documents will be most useful to industry when environmental questions or challenges arise.

An important conclusion is that redissolution of precipitated barium-radium-sulfate in contact with water exposed to atmospheric CO_2 poses a potential long-term environmental problem. The KEY LAKE MINING operation resolved this question by returning the precipitate to the tailings pond where they employ a "dry" tailings technique which, with their ore type, yields an impermeable tailings material in which the Ba-Ra-SO_4 will not be exposed to water saturated with CO_2. This is described in Appendix I.

Conclusions arrived at with respect to alternative radionuclide control technology other than those based on either in situ precipitation of $(BaRa)SO_4$ or adsorption of radium onto barite include:

- Solvent extraction shows little promise of removing Ra-226 from process effluents.
- Reverse osmosis can reduce Ra-226 to below 3 p Ci/l, but it produces a concentrate requiring further treatment.
- Ion exchange shows the most promise for removing one or all of radium-226, thorium-230, and lead-210 from conventional uranium process effluents as well as from leach liquors produced from the non-conventional processing of uranium ores.
- For acid and carbonate process effluents, the use of solid ion exchangers, zeolites, or strong acid cation resins will probably reduce the level of the nuclides to environmentally acceptable levels.
- Strong acid cation exchange resins may also be effective in removing the radionuclides from chloride, nitrate, or EDTA non-conventional process liquors if acid and total anion levels could be maintained to give effective extraction.
- Separation and purification of radium-226, thorium 230, and lead-210 may be accomplished by the proper choice of resins and eluting resins.
- The cost of non-conventional leaching of radionuclides, e.g., EDTA or uranium plus radium by nitric acid, requires significantly greater capital and/or operating costs than the conventional processes for uranium extraction.

RADIUM LEACHING WITH NaCl

RYAN and LEVINS (1979) described a process to rapidly leach radium from uranium tailings using 3M NaCl solutions. The radium is rapidly leached at ambient temperatures by either multi-stage contact in agitated vessels or by washing on a tailings filter cake. Extraction efficiencies ranging from 80-94% have been measured for tailings derived from a number of Australian ores. Extraction of radium with sodium chloride offers the following advantages claimed by the authors:

- The low cost of chemicals.
- Extraction occurs at ambient temperature.
- Rapid kinetics of extraction.
- Low consumption of reagents by gangue minerals.
- The process is easily adapted to conventional mill flowsheets and to existing tailings piles.

COMPOSITION OF AUSTRALIAN TAILINGS

		Tailings						
Ore	% U In Ore	% U	Ra-226 (Bq/g)	Sulfate mg/g	Stages Required	NaCl Conc (M)	Radium Extracted	Residual Ra-226 (Bq/g)
Ranger	0.217	0.023	28.4	8.7	4	5	91	2.6
Jabiluka	0.44	0.021	52.4	8.9	5	3	90	5.2
MKU	0.12	0.010	11.4	19.9	6	3	80	2.3
Nabarlek	1.42	0.048	189.9	6.0	11	3	94	11.4
Koongarra	0.375	0.026	41.3	7.8	8	3	80	8.3

Several methods for radium recovery from the NaCl leach were tested:

- Ion Exchange (Dowex AG-50W; Dowex AG-1; Chelex 100)
  Chelex 100, a weak acid resin, was effective in either the sodium or barium forms for radium removal. Radium dissolved from one ton of tailings could be recovered onto 20 Kg of Chelex resin. The resin could be regenerated by passing three bed volumes of 1NHCl through the column.

  Sulfate removal was not satisfactory for all the resins tested. Only Chelex 100 in the barium form retained sulfate to any significant extent and even with this resin, there was some immediate breakthrough of sulfate.

- Barium Chloride

Sulfate removal was almost quantitative for barium chloride additions in excess of twice the stoichiometric requirement. The efficiency of radium removal decreased in excess barium chloride. The authors suggested this might be because the radium was leached from the precipitate by the barium ion. Kinetics of precipitation are quite slow, and residence in excess of one hour is needed for maximum sulfate removal. Radium and sulfate precipitation were not affected by pH in the range 3-8.

Close control of $BaCl_2$ addition is required in an extraction plant to preserve an optimum balance between radium and sulfate. In practice, multi-stage precipitation has proven more satisfactory. In the first stage, stoichiometric $BaCl_2$ additions precipitate most of the radium while in the second stage, additional barium chloride would complete the sulfate precipitation. Alternatively, RYAN and LEVINS (1979) suggested that the process could be optimized for sulfate removal and the residual radium removed by either ion exchange or adsorption.

An obvious disadvantage of extracting and recovering radium from uranium ores is that the precipitates formed now will be concentrated and require special handling and disposal considerations.

RADIUM ADSORPTION ON $BaSO_4$ BARITES

ARNOLD and CROUSE (1965) established that barium sulfate adsorbs radium from effluent waters. To determine the efficiency of radium adsorption from 3M NaCl solution, powdered barium sulfate was agitated for one hour with a solution containing 5,300 Bq/l of Ba 226. Maximum radium removal was 80%, and this required 0.01 moles $BaSO_4$ per liter of solution.

RADIUM ADSORPTION ON MANGANESE

MOORE and REID (1973) described the use of manganese impregnated acrylic fiber for the removal of radium from seawater. A sample of this fiber was obtained from the U.S. Naval Oceanographic Office and tested for radium removal from 3M NaCl solution. One hundred and twenty superficial bed volumes of solution were passed through a column containing the fiber without breakthrough. This method of radium removal appears promising for the removal of residual radium before leach liquor is recycled according to RYAN and LEVINS (1979).

In the late 1970's or early 1980's at one or another meeting called to discuss uranium mill tailings disposal technology, the observation was made in discussion that radium can very

efficiently be removed by adsorption on manganese oxides. No reference or further mention of this technology has been found, however.

If tests were to confirm the usefulness of manganese as a radium adsorbent, then some of the coated sand media applications mentioned in Chapter 43 on manganese could be of interest also in radium removal.

RÖSSING URANIUM LTD.

RÖSSING URANIUM LTD. is an example of a large uranium operation in an extremely arid location where fresh water availability is limited. Numerous measures are adopted to reduce the fresh water needs, mainly through a greater degree of solution recycling. RÖSSING has reduced its net fresh water consumption to 0.39 m^3/t ore in 1984 which is a truly remarkable achievement. There are, however, several metallurgical effects that result from this that are described in a trip report in Appendix 1.

The RÖSSING URANIUM LTD. tailings dam is unlined and is constructed by spigotting tailings as a pulp at the dam wall. The dam is porous, and there is a significant flow of seepage water which is intercepted by trenches around its base. It is noted, however, that the quality of this water after it has percolated through the carbonate-rich sub-strata is significantly improved in that the acid content is neutralized, and several contaminants are reduce, for example:

	Tailings Dam Solution	Collected Seepage Water
pH	1.6	6.6
TDS ppm	33,000	13,500
Cl^-	880	960
$SO_4^=$	21,000	8,100
F^-	100	40
Fe	1,800	0.1
Mn	1,900	1,100
K	260	70
Silica	320	27
U_3O_8	17	0.5
Radium-226 p Ci/l	230	21.0

Although the effect of calcerous substrate is wellknown, the above data has not been officially confirmed and should please be kept strictly confidential.

Groundwater quality is carefully monitored around the property, and data shows that deleterious elements are satisfactorily attenuated well within property limits to the satisfaction of the regulatory authorities.

Of interest in the crosscut sections of the calcerous rock strata that are exposed by the seepage collection ditches is to see manganese precipitating out in the fractures. This manganese also seems to act as a good adsorbent for radium although no quantitative data was available other than the excellent removal of uranium and radium from the solution as it seeps through the underlying rocks. Undoubtably, as the seepage migrates further from the sampling point referred to above which was very close to the toe of dam, further attenuation takes place.

The RØSSING URANIUM main plant IX plant has been under scrutiny ever since the plant was commissioned because the IX tails are higher in U_3O_8 than are most other CIX plants around the world. Increased use of recycle water results in a further deterioraton in uranium recovery efficiency. ROSSING URANIUM LTD. operates a second CIX plant to scavenge additional uranium from the tailings decant water before it is returned to the plant for reuse. It is emphasized that in the current depressed uranium market, this operation must tune for optimum economics rather than optimum recovery. Most of the uranium that escapes primary CIX adsorption and also escapes the tailings solution CIX plant returns to the plant, and there is a good chance of recovering it there.

Unquestionably, the use of RDS recycle results in TDS concentration with increase in concentration of ions competing for sites on the IX resin. Silica levels are also higher in the pregnant solution, but it does appear that RØSSING has learned to achieve results that would have been considered impossible in the uranium industry just a year or two before. Some data was previously published on the CIX performance on RDS solution but, since the amount of recycle has been increased, this would have changed. RØSSING has not released present performance data.

THORIUM REMOVAL

ITZKOVITCH and RITCEY (1979) concluded that:

- Neutralization of acid mill effluents to pH 5 or higher adequately controls soluble thorium-230.

- No added treatment is required to control thorium-230 in carbonate mill effluents.

COTTER CORPORATION, SCHWARTZWALDER MINE (SEE APPENDIX I)

Water quality limits set in COTTER CORPORATION's operating permit (NPDES through the Colorado Dept. of Health) for their Schwartzwalder Mine would appear at first glance to present an almost impossible technical task. Much to the embarresment of the technical experts who said that there would not be an economically viable solution, the permit conditions have been met and according to all concerned, reliably. These effluent discharge limits (30-day average) are shown in the following table along with the composition of the feedwater and the treated effluent that is discharged (PALMER, et al, 1984).

Element	Feed (mg/l)	Typical IX Effluent (mg/l)	Discharge Limits mg/l 30d Ave.
Uranium (Dissolved)	2-7	0.01-0.02	0.06
Cadmium	0.002	0.0004	0.0004
Copper	0.02	0.005	0.005
Lead	--	0.005	0.032
Zinc	0.0026	0.05	0.05
Radium 226+228 p Ci/l	50-100	5	5 Total
Sulfate	800	800	N/A
Chloride	60	60	N/A
Barium		1.0	1.0
Arsenic		0.05	0.05

The continuous downflow ion exchange system that has been installed to achieve these remarkable results at a flow rate of 500 U.S. gpm in which uranium is reduced from 3-3.5 ppm U_3O_8 to 10-20 ppb U_3O_8 is described in the trip report on the COTTER CORPORATION in Appendix I using two 10-12 foot high resin columns in series.

Radium is removed using the now conventional $BaCl_2$ dosing technique. Coagulants are added in a mixing tank downstream from the surge tank, and $BaCl_2$ is dosed directly to this surge tank. This is followed by clarification in a 35-foot outdoor conventional clarifier and indoor filtration through two deep-bed sand filters. Particulates are dropped at this stage to around 0.2 ntu's. To achieve this low suspended solids level, both anionic and cationic NALCO polymers are added. Clarifier underflow sludge is dewatered on a drum filter and added to the ore. Sandfilter backflush sludges are returned to the clarifier.

A unique feature of the CIX system is acidification of the loaded resin in a transfer vessel located between the loading and elution steps. The acid (spent eluate) washing of resin serves to dissolve any carbonates from the resin and vents CO_2 in the transfer

vessel. This avoids CO_2 generation in the elution column where gas bubbles would cause channeling and impair performance.

Another remarkable aspect of the CIX performance is that 12 g U_3O_8/l eluates are generated from feedwater of say 3 mg/l U_3O_8 yielding a product water with 10-12 ppb U_3O_8.

The main points on COTTER CORPORATION are therefore:

- Extremely tight limits for U_3O_8 in effluents that are discharged, especially for uranium and cadmium.
- Extremely low level U_3O_8 in treated effluent.
- Remarkable concentration ratio achieved by the HIMSLEY CIX system installed at COTTER CORPORATION. Elution grade is high enough for the concentrate to be shipped directly as preg solution to the uranium recovery circuit at Canon City.

QUIVIRA MINING CO., AMBROSIA LAKE, NEW MEXICO

Despite the fact that the QUIVIRA MINING COMPANY is located in a very arid climatic region, water shortage is not a problem at Ambrosia Lake from a mill operating standpoint. In fact, the six mines must be dewatered, and excess water must be treated

to remove uranium, radium, and selenium before it can be discharged to a "creek" from which most seeps back underground in some kind of a macro-recycle loop.

Uranium is recovered from minewater by continuous ion exchange but as the TDS has built up in concentration over several years, e.g., $SO_4^=$ and Cl^-, so uranium loading on the two-stage fluid-bed KERR-MAC columns is depressed, and tail levels of U_3O_8 have been more difficult to keep down. To maintain 1 ppm U max. in the effluent, resin must now be eluted up to 100 times per month compared with about 16 times when the plant was first designed.

Water balance at the mill is regulated on the level of chloride in mill water. Cl^- is added to the system as 0.6 M NaCl used to elute the loaded solvent extraction SX organic phase.

Excess mill water is evaporated so it does not have to be treated for discharge as an effluent. This is possible because the operation is located in a climate with significant net evaporation. This requires very large and expensive impermeable ponds, however.

Tailings pond solution is recycled to some extent. The tailings dam is relatively porous, and it appears that a considerable degree of water seeps into the mines ultimately to be pumped out again.

Minewater, after IX removal of U_3O_8 and radium precipitation with $BaCl_2$, is stored in a series of ponds where biological processes remove some U_3O_8, Mo, and Se as described by BRIERLEY, et al. (1980) and BRIERLEY and BRIERLEY (1980). Although in the non-engineered way these biological processes work in the ponds, they do not seem to be super efficient. Nevertheless, there is evidence that there are definite biological mechanisms for contaminant removal at work in these ponds. Filamentous spirogira and benthic chara, both algae, were identified as acting as biofilters for U, Se, and Ra. Death and decay of the algae was found in lab studies not to result in the return of cell-bound U and Mo to the water due to the reducing conditions in the pond sediments which precipitate U and other metals. The recirculating minewater in effect acts as an in situ leaching process, and the IX recovery system produces about 100,000 lbs. U_3O_8/year.

This is an example of where a multi-stage CIX recovery system would perform better than the one or two-stage KERR-MAC Systems employed here. Multi-stage systems achieve better uranium recovery from solutions with high competiting ion concentrations.

Additional information would be available from:

BEISA MINE LTD., SOUTH AFRICA

The Beisa Mine located south of Welkom, South Africa, produces gold and uranium from Witwatersrand-type ores. Minewater at this mine is high in chlorides (up to 2,080 ppm CL^-) and has around 4,000 ppm TDS.

The gold mill employs carbon in pulp after cyanide leaching. The uranium plant employs sulfuric acid leaching followed by belt filtraton.

Operators find that the high chloride level allows a 20% faster rate of filtration than when the OFS Water Board fresh water is used.

The uranium plant IX recovery system is designed to operate at high Cl^- levels, and the operators claim that the plant is operating to design specifications which probably took the high Cl^- levels into account.

Rather than treat the large volumes of excess water pumped from underground at Beisa, evaporation has been found to be more cost effective as described by BENTAL and JAMES (1983).

DENISON MINES LTD.

At DENISON MINES LTD.'s Elliot Lake operations, minewater is used to encourage the leaching of uranium from the mine stopes. Low pH oxidizing solution is sprayed onto mine walls and collected for uranium recovery. 5,700 m^3/d of underground minewater is treated in the metallurgical operations to recover incremental uranium values. Minewater contains around 104 ppm U_3O_8 and 60 p Ci/l total radium-226. The uraniferous mine solution is used in the mill.

Excess precipitaton over evaporation at Elliot Lake requires that excess water decanted from their tailings pond must be discharged back to the lake system via Quirke Lake.

Data provided by DENISON MINES LTD. did not include a maximum value for uranium in discharged effluents, although there are regulated limits for radium:

	URANIUM, RADIUM Max. [Ra]
AECB Licence, Grab Sample	5.0 p Ci/l
Federal Metal Mine Regulations	
Monthly Average	10.0 p Ci/l
Annual Average	5.0 p Ci/l
Composite	10.0 p Ci/l
Grab Sample	15.0 p Ci/l

The Canadian federal limit on radium-226 in drinking water is 27 p Ci/l.

Radium is removed from tailings decant effluents at DENISON MINES LTD. by adding $BaCl_2$ to precipitate $BaRaSO_4$. DENISON has observed that the amount of radium in the final effluent is a function of the volume of the effluent. Radium dissolves in quantities that are a function of the amount of water in the mill. If ore is washed in fresh water, radium continues to leach from the ore.

At DENISON, it is found that the solids fraction of mill tailings contain an average of 256 p Ci/l. After neutralization, the liquid fraction in the mill tailings contains 1,411 p Ci/t, i.e., 1.4 p Ci/l, and 4,000 mg/l $CaSO_4$, mostly as $CaSO_4$.

Before addition of $BaCl_2$, soluble radium in the decanted tailings effluent runs around 370 p Ci/l. After a few weeks of aging, the dissolved radium in the pulp drops to 125 p Ci/l as the remainder attaches to solid particles. Even if aged another 20 years, if the tailings are not chemically altered, saturated pore solution stabilizes at around 120 p Ci/l.

At very high pH values, $BaRaSO_4$ flocs don't settle as well as at low pH. Also, the higher the sulfate concentration, the more effective radium removal is found to be. When adding $BaCl_2$, more gypsum and $SO_4^=$ is removed from the solution than would have been expected.

Concentration of radium in the settled sludge when precipitated at higher pH is diluted by gypsum that also precipitates, and radium may be present at hundreds of p Ci/g rather than thousands in the precipitate.

If $BaCl_2$ is added to a slightly acid effluent, radium precipitaton is said to work more efficiently than when $BaCl_2$ is added to high pH pulps and effluents.

Precipitation of $BaRaSO_4$ is also pH dependent like all sulfate precipitation reactions. When lime is added to an acid uranium leach effluent solution, a range of species such as $CaSO_4$, $BaSO_4$, and Ca-$BaSO_4$ will precipitate. The precipitation on addition of $BaCl_2$ at

pH 5-6 goes faster than at high pH's. When $BaCl_2$ is added to high pH solutions, the main species that precipitates is $BaSO_4$.

When $BaCl_2$ is added at a lower pH range, say 5-6, two results are noted:

- More radium is precipitated.
- Ba-Ra-SO_4 precipitates in a bigger volume of precipitate.

DENISON MINES adds $BaCl_2$ to their effluent at pH 8 and does not have a final pH adjustment like RIO ALGOM's Panel operation where provision is made for lime addition right before the $BaCl_2$ addition. Denison's final effluent averages about 3 p Ci/l Ra or less.

RIO ALGOM LTD., Elliot Lake

The behavior of radium in tailings pulps at Elliot Lake has been studied under various conditions by:

AL J. VIVYURKA
Senior Environmental Engineer
Rio Algom Ltd.
Post Office Box 1500
Elliot Lake, Ontario
Canada P5A 2KA
(705) 461-2518
Telex: 067-7338

Early work at RIO ALGOM LTD. dating to 1972 was reported by DUNN, et al. (1972) which may describe useful evaluations. Rio Algom Ltd. has installed a large effluent treatment plant at Elliot Lake, but this was not visited, and precise results were not obtained as the opportunity to return to Elliot Lake for a third time as planned did not materialize. Nonetheless, when considering alternative approaches for radium removal, the Rio Algom effluent plant should be considered.

After $BaCl_2$ addition to the tailings pulp, radium drops to 3.3 p Ci/l average. The ratio of total to soluble radium varies depending on conditions. Radium settles out as $BaRaSO_4$ precipitate in which the radium level typically falls in the range 500-5,000 p Ci/g.

According to CHAKRAVATTI (1984, personal communication), the amount of residual soluble radium in an effluent is virtually independent of the $BaCl_2$ dosage. More critical is how the $BaCl_2$ is added, e.g., contact time, settling capacity, pH, etc.

Multistage $BaCl_2$ additions to effluents are practiced at both RIO ALGOM LTD.'s Quirk uranium plant at Elliot Lake and at KEY LAKE MINING's operations in Saskatchewan.

RABBIT LAKE OPERATIONS, SASKATCHEWAN

Ra is removed from solution by $BaCl_2$ addition which precipitates $BaRaSO_4$.

A change in ore type from the original Rabbit Lake ore to Collins "B" zone required a whole new metallurgical process which is described in Appendix I.

More information on the effectiveness of the new process with respect to heavy metals, arsenic, radium, and uranium removal from effluents could be requested from:

KEY LAKE MINING CORPORATION, SASKATOON

Key Lake processes a very high grade uranium ore which also contains high levels of other contaminants such as nickel, arsenic, and radium.

KEY LAKE MINING LTD. operates an innovative water treatment plant to precipitate arsenic and nickel which employs an interesting approach achieving some of the same effects as a high density sludge process by adding lime in stages to flash mixers between each neutralization tank, ending at pH 11 and over.

Following bulk neutralization of the effluent using lime, the effluent is neutralized by adding H_2SO_4 to pH 7, and then $BaCl_2$ is added in stages and achieves in hours what at other uranium mines such as at Elliot Lake and Rabbit Lake takes days or weeks. The Key Lake radium precipitation plant arrangement is depicted in the following diagram. $BaCl_2$ addition has also been found to precipitate arsenic to 0.1 ppm As.

Following bulk neutralization and radium precipitation, KEY LAKE MINING retains the treated effluent in ponds where it can be tested to ensure that it meets effluent limits stated in their permit before it is released to the receiving waters. If not, it is recycled to the front of the treatment process.

KEY LAKE has employed a layered "dry" tailings disposal technique which, as the tailings dry out, results in a tailings material of extremely low permeability. This type of tailing provides a very effective encapsulation of sludges recovered after water treatment. More can be learned about this type of tailings disposal in the Appendix I trip report and from:

Sludges of base metal and arsenic precipitates generated in the water treatment process may become unstable in time if simply disposed of in a pond. ROBINS and TOZAWA (1982) and ROBINS (1984a) pointed out that although barium arsenate is very unsoluble when freshly formed, it may be destabilized by CO_2 from the atmosphere in equilibrium with pondwater.

Encapsulation of sludges in the super-impermeable tailings using the sub-aerial technique mentioned above overcomes this possibility very effectively as neither CO_2 nor water can get to the sludge, nor can solutions seep from the tailings pond material once they have been decanted and dried.

This "semi-dry" or "subaerial" tailing disposal method works best in net precipitation climates, however, and the effectiveness in the field at Key Lake was not investigated firsthand, although simulated pilot scale testwork showed very promising results.

JABILUKA URANIUM OPERATION, ALLIGATOR RIVER AREA, NORTHERN TERRITORY, AUSTRALIA

Contaminant concentrations in a typical Alligator River ore treatment facility in Australia before and after lime treatment were reported by LEVINS (1979) for Jabiluka tailings-raffinate slurries.

$SO_4^{=}$	25,000-50,000	2,000-8,000
Ra (Bq/l)	5-25	3-15

It is clear that lime addition to pH 8 is effective in the presence of Fe and other co-precipitatants in reducing residual uranium values to below 0.1 mg/l. It is not, however, as effective in precipitating radium, even though the effluent contained only 0.1-1 mg/l Ba. The addition of 10 mg/l $BaCl_2$ before or after the addition of lime would undoubtably reduce radium further.

The following curve from LEVINS (1978) shows how several metals including uranium are effectively removed in lime-treated Jabiluka tailings-raffinate slurries.

EAST RAND GOLD AND URANIUM CO. LTD. (ERGO)

ERGO recovers gold, uranium, and pyrite by re-processing 1.6 million tons of slimes per month from tailings dams left by earlier gold mining operations on the East Rand.

This operation produces a significant amount of uranium by acid leaching the roasted pyrite concentrate recovered from the tailings by flotation.

Uranium, radium, and radionuclides in tailings and effluents are not amongst the several water balance and effluent treatment challenges and innovations at ERGO. These elements, at the low levels at which they occur in ERGO tailings and effluent, are not of concern to regulators after careful scrutiny.

VAAL REEFS EXPLORATION AND MINING COMPANY LTD.

A trip report describing Vaal Reefs is included in Appendix I to summarize water management practices and treatment technology employed at this huge multi-mine and multi-mill complex which treats close to ten million tons of mined ore per year.

As at ERGO, this major uranium producer experiences no problems with uranium and radium in its effluents and tailings. In fact, these elements do not even appear on the list of elements and ions to be monitored in the various effluent streams.

It is believed that this is because the levels are so low that they have been deemed, appropriately, non-detrimental to the environment.

URANIUM MINE, WASHINGTON STATE

A uranium mine subsidiary of a major mining house is currently shut down for economic reasons based on the price of uranium.

Ear Craig, who retired from DAWN MINING several years ago, recalls that multi-media filter containing a bed of anthracite coal was employed to clarify pregnant feed liquors ahead of the ion exchange plant.

A routine radioactivity survey many years ago found that this coal filter bed had become highly radioactive. It is possible that radium-226 in the pregnant solution had been building up for some time. This took place many years ago, and none of the professional staff working there when the plant shut down had any recollection of the anthracite filter. What is important about it is that anthracite coal may be worth testing as a means of removing radionuclides from effluents.

The DAWN MINING operation is located in an area with a net precipitation, and it is consequently not possible to operate on a zero-discharge basis. Before the tailings pond was lined in 1982, there was adequate leakage from the pond to bring their water into balance. This leak also provided an adequate bleed of salts so that these did not build up excessively. After the pond was lined, however, much more tailings decant water had to be recycled to avoid filling the dam to capacity prematurely. As a result, dissolved salts steadily built up in the water. This had a definite effect on the efficiency of uranium recovery on the ion exchange resin. This was partly due to competitive ions in the process water and, it is believed, partly due to silica buildup on the resin which caused fouling. These factors, combined with a reduction in uranium price, contributed to the decision to suspend operations. Although undoubtedly the tailings pond decant liquor contains some U_3O_8, no mention has been made of the need to discard excess water

as an effluent since the plant shut down or to remove uranium from effluents. If the plant starts up again, eventually an effluent will probably have to be treated.

RADIUM REMOVAL: LITERATURE SEARCH

A search of Chemical Abstracts and Waterlit produced the following:

HUCK, P. (1982) of the Engineering Dept., the University of Regina, reviewed effluent treatment from Canadian uranium mining and milling operations to remove Ra-226. Historically, treatment has been by adding $BaCl_2$ to form a finely divided precipitate of $(Ba,Ra)SO_4$ which is then settled in large ponds or lakes. He discusses improvements to conventional pond systems as well as a new mechanical solid liquid separation device incorporating co-precipitation and solids separation.

Ion exchange provides an alternative to systems based on co-precipitation by $BaCl_2$ addition.

Ra removal during mill processing is discussed as a potential long-term alternative to effluent treatment by HUCK but does not look too encouraging.

AVERILL, et al. (1981) of the Wastewater Technology Center of Environment Canada at Burlington, Ontario, established a data base for the design of two alternative wastewater treatment processes for the removal of Ra-226. Both of these processes achieved less than 0.37 Becquerel/l of total Ra-226 and dissolved Ra-226 of less than 0.11 Becquerel/l. The clarification process of Ba-Ra co-precipitation, rapid mixing of a chemical coagulant, flocculation, and solid/liquid separation in a clarifier could operate at a load of 490 m^3/m^2 day. The process using Ba-Ra sulfate co-precipitation and solid/liquid separation in a granular media filter could operate at a hydraulic load of 6.5 l/m^2s.

RYAN and ALFREDSON (1976) of the Australian Atomic Energy Commission at Lucas Heights, Australia, compared lime, limestone, caustic soda, and lime-soda ash mixtures as reagents for neutralizing raffinates and for removing amines and heavy metals including Ra from solution. All methods of neutralization reduced contaminant levels significantly. Two-stage neutralization with limestone in the first stage, followed by lime, usually gave the lowest residual Ra concentration, provided the solids from the first stage were not removed before adding lime. Ra can be further reduced from neutralized raffinates and from mine water conditioned with SO_4^{2-} by the addition of $BaCl_2$ to less than 3 p Ci/l by adding 10 mg Ba/l raffinate. For mine water containing 0.01 M SO_4^{2-}, Ba additions of 20 mg/l were required to attain the same Ra concentrations. Adsorption on barite was also effective in removing radium from conditioned mine water and neutralized raffinates.

SHERWOOD and CERN (1983) reviewed the treatment of uranium mill tailings and effluent in NUREG CR 2938, PNL 4453 of July 1983. The authors are employed at:

DIVISION OF HEALTH, SITING, AND
WASTE MANAGEMENT
U.S. Nuclear Regulatory Commission
Washington, DC 20555

CAMPBELL and SKEAFF (1982) characterized barium/radium sulfate sludges from uranium mining effluents. Based on bench-scale tests, they identified unexpected differences among the dewatering characteristics of several $BaRaSO_4$ sludges. Although these sludges resulted from the same basic waste treatment process (addition of $BaCl_2$ for precipitation of Ra-226) and the same minewater, the process configuration, i.e., settling pond, clarifier, sand-filter, etc., had a significant impact on the characteristics of the resulting sludge. This fact, in conjunction with the proposed ultimate disposal option, should play a major role in choosing a dewatering system. A freeze-thaw process resulted in the greatest degree of volume reduction for sludges with high specific resistances.

H. W. Campbell and J. M. Skeaff are employed at the Environmental Protection Service, Division of Environment Canada, at Burlington, Ontario.

WATER QUALITY AND MANAGEMENT IN FROTH FLOTATION

Water quality and water management has a significant impact on recovery, grade of concentrate, and effluent quality in flotation processes. Flotation of mineral particles from gangue, or one mineral from the other, makes the use of their different surface properties. These properties are modified or adjusted through the use of reagents. It is not surprising that water chemistry will influence the performance and selectivity of the flotation process since water is the suspension media with which the milled ore is in contact.

What is surprising is how little is generally known about the effect of various contaminants in water on the process and on the mechanisms for these effects.

Technical treatises on the flotation process rapidly become complicated and theoretical. In the end, the operator or researcher who is faced with a problem usually reverts back to empirical test results anyway.

FLOTATION OF MINERALS

Flotation is typically used in mineral processing to separate valuable sulfide minerals, e.g., chalcopyrite, galena, stibnite, sphalerite, pentlandite, native silver, silver sulfides, and molybdenite from gangue minerals such as quartz, limestone, dolomite, schist, and/or clay minerals, micas, etc.

These types of separations are typically employed in the treatment of copper porphyry and massive sulfide ore deposits in Chile, Zambia, Southwestern U.S.A., Canada, and South Africa.

Separation is also used to separate one sulfide mineral from another from bulk or semi-bulk concentrates, e.g., galena from copper minerals, molybdenum from copper minerals, or base metal sulfides from iron sulfides.

Separation of one sulfide from another by flotation is typically employed in the recovery of separate concentrates from complex sulfide ore such as occur across the Canadian Shield (Cu, Pb, Zn), in Sweden, Australia, and South Africa. Sulfide separations are also employed to separate copper-molybdenum bulk concentrates.

At Kidd Creek Mines, Timmins, Ontario, a flotation unit is installed in the secondary grinding circuit to float metallic silver particles which otherwise would be returned with clarifier underflow streams to the mill and would eventually be overground unless removed by this innovative flotation step.

Froth flotation is employed to recover non-sulfide minerals from gangue as, for example, in the recovery of Foskorite from carbonatite rocks at Phalaborwa or fluorspar from gangue, or in the recovery of Barytes.

Gold is recovered in free metallic from and/or in sulfide minerals, e.g., arsenopyrite or pyrite from a variety of ore types and/or from cyanided tailings.

Flotation can also be used to remove impurities, e.g., ferromagnesian minerals from silica sand where high purities are required for the glass and other industries.

There is clearly a very wide range of applications of flotation processes. All of these can be influenced by water quality effects.

Here there is room to refer to just some of these applications and to follow by inserting a few review papers which could provide useful insight into some of these effects. Clearly, a book could be devoted to this topic alone.

Brief comments on the following flotation applications follow:

Copper from Porphyry Deposits
Molybdenum
Copper-Molybdenum
Lead-Zinc
Copper-Lead-Zinc
Phosphate-Copper
Pyrite-Gold from Tailings

FACTORS INFLUENCING WATER QUALITY

Several factors influence the quality of water in flotation plants:

- Quality of available makeup water for use in the mill. Minewater, seawater, well, or lakewater.
- Dissolution of contaminanats from the gangue or mineral species.
- Flotation reagents or their degradation products.
- Tailings pond reactions and influence on recycled water quality.
- Degree of recycle water use and where it is used.
- Biological processes.

MOTIVATION AND EFFECT OF SOLUTION RECYCLING

Increasingly, strict effluent discharge regulations make it more or less mandatory in the U.S.A. to operate with zero discharge where climate allows. This means that water must be recycled or evaporated. Where climatic constraints do not allow zero discharge, effluents must be treated before they are discharged in order to meet the rigorous effluent contaminant levels that are required. This can be very expensive as well as difficult. The economic pressure of meeting these regulations is, therefore, also toward greater use of recycled solution.

When tailings decant solution is recycled, common contaminants that build up in the solution include:

Sulfate Ions
Sulfide
Thiosalts and Thiosalts
Alkaline Earth Elements Mg^{2+}, Ca^{2+}
Base Metals, e.g., Cu^{2+}, Zn^{2+}, Ni^{2+}
Reagents, e.g., Collectors, Frothers, Activators, Depressants, and their Degradation Products

Before solutions had to be recycled, it was common practice to use hexavalent chromium as sodium dichomate as a depressant in the separation of galena from lead-copper semi-bulk flotation concentrates. $Cr^{(VI)}$ is a powerful depressant for galena and, if even traces were to get into the main recycle water stream, this would result in loss in lead recovery in the primary concentrate.

Also, since hexavalent chromium is very soluble and toxic, its use would render tailings "hazardous" under the EP toxicity test which would require special disposal and management procedures. This is but one example of the need for a knowledgable use of a systems approach in managing water in mines and mills using flotation processes.

Another example of this is soluble copper in complex sulfide flotation flowsheets. For example, if water is recycled many times, small incremental levels of copper may dissolve from interaction with the ore until eventually a high enough level is reached to activate sphalerite in the primary semi-bulk float--just where, in the processing arrangement, depression of sphalerite is wanted. Soluble copper is used to activate sphalerite later in some circuits in the final zinc recovery step. If this soluble copper finds its way back to the front of the circuit, this could have the same undesired result. Copper can also get into mill process solutions if ores contain even small fractions of soluble oxide copper. This was a startup problem at the VAJASA concentrator on the Yukon border.

Similar considerations have to be taken into account for a host of ionic and organic species that are used or can find their way into solution.

The comminuted mineral surfaces first come into contact with water in the grinding circuit. In some cases, it has been found that even if the millwater is replaced with deionized water as it leaves the mill, the flotation characteristics will be affected by the composition of water in the mill. This, of course, is not usually the case, but some flotation separations are much more sensitive to water quality in the float cells than others. Another important aspect is the effect of water and air oxidation of surfaces on

flotation and water quality. For example, WASSERLAUF and DUTRIZAC (1982) and others showed that much of the thiosalt generation in flotation pulps occurs in the float cells and can be avoided if a nitrogen atmosphere is used. Aeration is often used as a preconditioning step in the separation of complex sulfides, however.

COPPER PROPHYRY FLOTATION

Copper sulfide minerals are recovered on a massive scale from porphyry deposits. All but one of the operations located in the southwestern desert region of the U.S.A. recycle as much water as they can recover from tailings as can be seen in the table below.

In these cases, scale control is important due to the use of lime for pH control and sulfate generation through oxidation of sulfides in the pulp and tailings..

Motivation to recycle water is due to to generally limited water availability in this region. Some operations, e.g., Phelps-Dodge at Morenci, recover 85% of the water calculated to be lost by seepage from their tailings pond via intercepter wells.

The simple metallurgical flowsheets used and the limited sensitivity of the single-component recovery process allows virtually 100% recycle of solution with the result that these operations consume only 80-105 U.S. gallons of net fresh water per ton of ore treated, i.e., 0.3-0.38 m^3/t. In these cases, over 85% of the total water used per ton of ore (2.3-2.7 m^3/t) is recycled.

On the other hand, where water is abundantly available or excess minewater must be disposed of in any case, a smaller percentage of water is recycled. The White Pine Copper Co. recycled no water. All decanted tailings water discharged lime-settling treatment.

Magma at Superior, one of the smallest copper recovery operations, delivers their excess water to local farmers for irrigation.

Before the Anaconda Co. shut down their operations at Butte, Montana, they were discharging 10 million gallons per day of decanted process water after pH adjustment with H_2SO_4.

COPPER-MOLYBDENUM FLOTATION

Somewhat sketchy information was gathered about water recycling at copper-molybdenum recovery operations from porphyry ore deposits in the southwestern U.S.A.

Water is usually recycled in the bulk copper-moly flotation step but almost never in the copper-moly separation step which uses a lot less water, in any case, because the volume of primary concentrate treated is only a small fraction of the ore milled.

Results of a rough survey of a few operations as to how much water they use and how much is recycled are shown on the table overleaf.

According to this table, all the southwestern copper-moly operations recycle all the tailings decant water that they can from their tailings pond.

However, it is interesting to note that:

1) Net fresh water consumption per ton ore for Cu-Mo operations ranges between 0.77-0.92 m^3/t (200-235 U.S. gpt). This is two to three times as much new water as is used by straight copper flotation plants.

2) In the copper-moly separation step, recycle water is not used as this process is much more sensitive to water quality as described by FISHER and RUDY (1976) and HOOVER (Post 1979) inserted below.

HISCOX and BUZA (1975) described a new lignin sulfonate application as a moly depressant at Twin Buttes copper-moly recovery operation. An important aspect of this is that it illustrates the powerful depressing effects of lignin sulfonate on some minerals--in this case, molybdenum sulfide. This is important as it has impact on the decision as to whether or not to use lignin sulfonate as a binder for dust control on mine haulage roads. If the mine road is built on ore which will be mined at a later date, the use of lignin sulfonate would have a marked detrimental effect on molybdenum recovery.

Others have reported that even small amounts of naturally generated lignin sulfonate, when it gets into the plant water stream, can cause disastrous results on flotation plants. Lignin sulfonate generated by mine timbers in contact with minewater used in a mill reputedly caused uncontrolled frothing resulting in concentrate discharging to the floor sump at a copper-moly mill in the U.S.A.

FISHER and RUDY (1975) showed that the use of reclaimed sewage water results in significant reduction in molybdenite recovery and grade when used for flotation. They showed that activated carbon and foam fractionation treatment of the sewage water only partially improved the flotation performance compared with demineralized water. HOOVER

(after 1979) showed that the reduced recovery was largely due to the presence of colloidal solids rather than organic molecules. See his paper inserted below.

SCALE CONTROL

When water is recycled from tailings where it has been in contact with sulfide minerals, especially once the pH is allowed to drop requiring lime neutralization on return to the high pH process circuit, TDS builds up, principally consisting of $SO_4^{=}$, Ca^{2+}, and Mg^{2+}. These solutions can be highly scale forming. Scale must also be controlled in the powerhouse and steam plant. Copper and copper-molybdenum operations all depend on water treatment specialist companies who do this as a contracted service, e.g.:

NL Industries, Barochem Division

Drew Company

Nalco Chemical Company

Calgon Corp.

Betz Chemical Company

SOUTH AMERICAN COPPER-MOLY MILLS

It is known that high-TDS water with a poor quality must be used at some South American copper-moly producers. Seawater has been used for copper precipitate flotation operations. At the sulfide flotation mill of Codelco's Chuquiquamata operations, it is believed that poor quality water is used due to the need to recycle water on account of poor availability of good quality fresh water. It is believed that reclaimed sewage water is also used in the mill.

The 90,000 tpd (1966) operation at Chuquiquamata employed four 350' thickeners for water recovery from the surface of which evaporation was calculated at 2,000 m^3/d on account of the high altitude and wind effects. Apparently the highly recycled water has high TDS levels which cause scale problems.

COMPOSITION OF TAILINGS DAM RECLAIM WATER

Reclaim water from the Duval Sierrita operations typically contains 1,400 mg/l $SO_4^=$ and Ca, Mg, and Cl^- in the 100-150 ppm range.

KENNECOTT MINERALS COMPANY, BINGHAM CANYON, UTAH

The Bingham Canyon operation milled 110,000 tpd ore to recover copper and molybdenum. Total water used in the circuit is 70,000 U.S. gpm (3.9 m^3/t) of which 40,000 U.S. gpm is "new" water (2.2 m^3/t). Of this, half comes from deep wells which yield an excellent quality water. The remaining 50% comes by surface canals from Utah Lake located in the Salt Lake City Valley.

MoS_2 recovery has been recognized since the 1940's to be subject to seasonal variation. During the hot summer months, MoS_2 recovery is poor, and in the cold winter months, recovery improves significantly.

MoS_2 recovery to the bulk Cu-Mo concentrate is 80-85% in winter but only around 60% in summer. In order to determine the cause of this, all variables (ore, reagents, water quality, etc.) were analyzed weekly over a two-year period. Organic and inorganic constituents of water were analyzed including residual reagents, humic acid (a depressant for molybdenum), and fluvic acid.

It was found that during summer, biological decay on farms resulted in 4-5 mg/l humic acid in the water supply to the concentrator. Humic acids were analyzed by loading them onto a Rohm & Haas resin and then stripping them prior to liquid chromatography determination.

UTILIZATION OF MUNICIPAL WASTE WATER FOR FROTH FLOTATION OF COPPER AND MOLYBDENUM SULFIDES

by
Walter W. Fisher, Assistant Metallurgist
and
Samuel Rudy, Assistant Metallurgist

INTRODUCTION

Water is becoming a more and more controversial subject in Arizona. The problem stems from the fact that the amount of water consumed far exceeds the ability of nature to replace it. In order to meet growing agricultural, industrial, mining and municipal demands, water is being mined from groundwater reservoirs at alarming rates. Statistics presented in Phase I of the Arizona State Water Plan recently released by the Arizona Water Commission indicate that for Arizona, taken as a whole, water is being withdrawn from groundwater storage at 1.7 times the rate at which it is being replaced by natural recharge. In Pima County, where essentially all water consumed is drawn from the groundwater supply, the depletion rate is 4.7 times the recharge rate. Such depletion of the groundwater supply cannot go on indefinitely. Alternatives must be found and implemented to narrow the widening gap between water use and water recharge.

One alternative that could result in a significant reduction in groundwater depletion near metropolitan areas is utilization of municipal waste water. This large source of water is presently used to a very limited extent. For example, in Pima County, the City of Tucson discharges about 33 million gallons per day of municipal waste water into the Santa Cruz River. Part of this water percolates into the ground and will ultimately enter the groundwater reservoir to the north of Tucson. However, a large portion of the water evaporates into the atmosphere. The City of Tucson is currently seeking alternative uses for this water. Of the many possibilities, the one that has received the most public exposure is utilization of the waste water by the four copper mining and processing operations located south of Tucson. This alternative would reduce the groundwater depletion in the area and at the same time provide the local copper industry with a reliable, long term source of water.

Municipal waste water is already utilized to a small extent in several copper processing operations in Arizona. However, the amount used is rather small when it is compared with the total water consumed by each operation and the adverse effects attributable to the waste water are not readily observed in these operations.

The proposed use of waste water by the operations near Tucson is considerably different. The water currently used by these operations would be almost completely replaced with waste water. The mineral processing techniques used by these companies are extremely sensitive to chemical contaminants, and therefore, large scale substitution of waste water could have serious detrimental consequences. Because there is not an industrial precedent for this type of municipal waste water utilization and since experimental studies on the effects of waste water in mineral processing have not been reported, there remains a large gap between proposed utilization and commercial acceptance.

The Arizona Bureau of Mines, under the sponsorship of the Office of Water Research and Technology at The University of Arizona, has for the past two years studied the feasibility of utilizing municipal waste water in mineral processing. The laboratory investigation has been aimed at first identifying potential problems, and then, seeking solutions that would be acceptable to the mineral processing industry. Since this work was prompted by a specific problem in the Tucson area, the investigation has been limited to utilizing City of Tucson municipal waste water in the mineral processing operations south of Tucson. The largest use of water in these operations is in the froth flotation recovery of copper and molybdenum sulfide minerals. Consequently, this entire report is devoted to the utilization of sewage effluent in the flotation process.

The work reported in this paper is by no means an exhaustive study of the problem. Rather, it is an exploratory study meant only to define the problem and point out areas for future concentrated investigation.

Background on Copper-Molybdenum Froth Flotation

Froth flotation is the principal process by which sulfide minerals are recovered from ores to form sulfide concentrates. The copper industry relies almost entirely on froth flotation for its feed to smelters and hydrometallurgical refining processes. The success of the flotation process lies in the carefully controlled addition of small quantities of specific chemicals to the processing system at the correct addition point. As a result, froth flotation is extremely sensitive to small amounts of chemical contaminants that may be present in water supplied to the processing system. Foreign chemical contaminants in the process water can have a significant effect on froth flotation metal recovery.

Flotation recovery of copper sulfide minerals and by-product molybdenum sulfide, as practiced in most copper concentrators, consists of many interdependent flotation stages. Raw ore, having been crushed and ground sufficiently fine, is subjected to the rougher flotation stage. A rougher bulk concentrate is produced which contains most of the copper and molybdenum sulfide minerals, along with other impurities. The rougher concentrate is ground finer, and cleaned two or three times by flotation to remove as much non-sulfide material or gangue as possible and produce a high-grade bulk copper-molybdenum concentrate. Molybdenum sulfide is then separated from copper sulfides by chemical treatment and differential flotation to produce a relatively low grade rougher molybdenum sulfide concentrate and a high grade copper concentrate. The rougher molybdenum concentrate is cleaned by several additional stages of flotation to further reject copper sulfides and gangue to produce a high-grade final molybdenum concentrate.

This report is devoted solely to the determination of the effects of sewage effluent on bulk rougher flotation. Therefore, the results presented serve only to identify the gross and most obvious effects of sewage effluent. Determination of the effects of sewage effluent on the integrated copper-molybdenum froth flotation processing scheme is beyond the scope of this report, and in fact, can probably only be determined with certainty in a pilot plant of sufficient size to allow scale up to commercial practice.

EXPERIMENTAL PROCEDURE

Ore, Water and Reagents

The investigation was conducted using an ore obtained from the Cyprus Pima Mining Company open pit mine located south of Tucson. Approximately 800 pounds of ore was collected in the concentrator from conveyors feeding three grinding mills in the primary grinding circuit. The ore was stage crushed in the laboratory to minus 10 mesh, mixed, split into 1000 gram dry test charges, and stored in plastic bags for later use. Since the ore samples were ground in a laboratory ball mill prior to each flotation test to produce an ore pulp containing about 47 percent finer than 200-mesh, oxidation of the sulfides in the minus 10-mesh ore during storage was not considered to be a significant problem. Chemical analysis showed the sample to contain 0.49 percent copper, 4.40 percent iron and 0.011 percent molybdenum. Chalcopyrite, pyrite, and molybdenite were identified microscopically as the main sulfide minerals present.

Demineralized water generated with a high-capacity Barnstead demineralizing column was used for the standard flotation tests. (Use of product or company names in this report is made for identification only and does not serve as an endorsement by the Arizona Bureau of Mines.) Water obtained by this procedure was designated standard water in subsequent flotation tests, and was used to establish a reference flotation response from which direct comparisons of flotation results could be made. Sewage effluent was obtained at the City of Tucson's Roger Road sewage treatment facility from one of the activated sludge units. All samples were collected from the same treatment unit between the hours of 8 and 9 A.M. so that the flow rate through the plant was essentially the same for each sample.

Flotation reagents used throughout the study were standard laboratory chemicals in general use by flotation laboratories. Potassium amyl xanthate (Z-6) and methyl iso-butyl carbanol (MIBC) were used as the primary collector and frother respectively. In some tests, American Cyanamid AERO PROMOTER 3302 was used as the collector. A mixture of 50 percent kerosene and 50 percent Number 2 diesel fuel constituted the fuel oil mixture. Hydrated lime assaying 93 percent $Ca(OH)_2$ was used as the pH modifying agent.

Flotation Procedure

Flotation tests were conducted in the following manner. One thousand grams of ore containing suitable additions of desired reagents were ground at 67 percent solids for 10 minutes in a 7.5 by 8-inch laboratory ball mill containing 30 pounds of steel balls of various sizes. The ground pulp was transferred to a Denver D-1 2.5 liter laboratory flotation cell and diluted to 2.2 liters or about 35 percent solids. The pH of the slurry was determined using a Corning Model 7 pH meter. The slurry was then conditioned for 2 minutes with the air valve of the flotation mechanism in the open position, after which time frother was added and the slurry conditioned another minute without introducing air. The conditioned pulp was subjected to rougher flotation with the impeller of the flotation machine rotating at 1800 RPM. Froth was drawn on 10 second intervals for 8 minutes. The sides of the flotation cell were washed on 2 minute intervals, and the pulp level was adjusted after 4 minutes by adding 100 milliliters of water. Rougher concentrate and rougher tailings were filtered, dried, weighed, and analyzed for copper and molybdenum using an atomic absorption method. Iron determinations were made by a standard volumetric method.

The procedure of conducting a standard flotation test with each series or set of sewage effluent tests was adopted to allow a direct comparison of results of the various test sets.

Experimental Approach

Most of the copper processing operations use complex reagent schedules that have been devised through several years of laboratory evaluation and plant operating experience. In general, each reagent schedule is tailored to fit the ore on which it is used with optimum flotation response as the goal. If an

optimum, multi-component reagent schedule was used in this investigation, some of the effects of sewage effluent might have been masked by the compensating ability of the reagent schedule. Therefore, a very simple reagent schedule was chosen for the initial flotation tests, so that the full effects of sewage effluent would be apparent.

RESULTS AND DISCUSSION

Development of the Standard Flotation Test

The development of a standard laboratory flotation reagent schedule and establishment of a standard flotation response was necessary to provide a basis from which comparisons could be made and metallurgical differences could be determined between sewage effluent and standard demineralized water flotation systems. Adequate liberation of sulfide minerals from host rock was the first consideration. Laboratory grinding studies indicated that a 10 minute grinding time provided adequate liberation and produced a particle size distribution that generally paralled that which mining companies in the area achieve. Table 1 shows the particle size distribution obtained for a 10 minute grind.

Table 1

Screen Analysis of Ground Ore

Tyler Screen Fraction	Weight Percent Retained	Cumulative Weight Percent Retained
+ 35	1.8	1.8
- 35+ 48	4.7	6.5
- 48+ 65	11.9	18.4
- 65+ 100	11.3	29.7
-100+ 150	10.4	40.1
-150+ 200	13.1	53.2
-200	46.8	100.0

Potassium amyl xanthate and methyl iso-butyl carbanol were chosen as the collector and frother respectively, because of their wide use in industry. Figure 1 shows copper and molybdenum recovery as a function of collector dosage at a pH of 11.5 with 0.04 pound per ton of frother. A collector addition level of 0.04 pound per ton was adopted as the standard collector dosage to be held constant throughout the study.

Flotation recovery for copper and molybdenum is shown as a function of pH for standard water and sewage effluent systems in Figures 2 and 3. These figures indicate that a pH in the range of 11.0 to 12.0 is optimum for copper and molybdenum recovery in both standard water and sewage effluent systems. A pH of 11.5 was thus selected as the pH at which the standard test would be conducted. Figures 2 and 3 also show that sewage effluent effects molybdenum recovery far more than it does the recovery of copper.

Iron in the rougher concentrate is contributed by both chalcopyrite and pyrite. Pyrite is generally an undesirable constituent of the concentrate and therefore flotation conditions are adjusted to reject as much pyrite as possible. A decrease in the iron content of the concentrate is an indication of pyrite rejection. Figure 4 shows the effect of flotation pH on the amount of iron contained in rougher concentrate for the standard water and sewage effluent systems. Pyrite depression is substantial but not complete at a pH of 11.5. In practice, a more complete depression of pyrite is generally achieved in the cleaner flotation section.

Table 2 summarizes the standard test reagent schedule developed during the initial stage of the investigation for comparing sewage effluent with standard water.

Table 2

Reagent Schedule for Standard Water and Sewage Effluent Flotation Tests

Addition Point	Reagents, pounds per ton					
	Standard Water			Sewage Effluent		
	Lime	MIBC	Z-6	Lime	MIBC	Z-6
Grind	3.5	----	0.04	4.0	----	0.04
Condition	---	0.04	----	---	0.03	----

The lime requirement necessary to attain a pH of 11.5 was greater for sewage effluent than for standard water. In addition, less frother was required to achieve optimum frothing conditions in the sewage effluent system than in the standard water system.

Standard Water and Sewage Effluent Test Results

Table 3 shows a comparative metallurgical summary for eight standard water and eight sewage effluent flotation tests conducted on different dates over a period of several months. The table illustrates the small but measurable detrimental effect on copper recovery, and a substantially larger detrimental effect on molybdenum recovery when utilizing secondary treated sewage effluent as process water in the systems studied. The percent recovery values have been calculated at the 95 percent confidence level. The magnitude of the losses attributable to sewage effluent can be dramatically reduced by the addition of certain supplemental flotation chemicals to the system, especially in the case of molybdenum.

In addition to the quantitative metallurgical differences between sewage effluent and standard water systems evident from Table 3, a very significant difference in frothing characteristics exists between the two systems. Sewage effluent causes a voluminous, dull grey colored initial froth (without the

Figure 3. Molybdenum recovery vs. pH for demineralized water (D. W.) and sewage effluent (S. E.).

Figure 4. Percent iron in rougher concentrate vs. pH for demineralized water and sewage effluent.

Table 3

Comparative Metallurgical Summary for Standard Water and Sewage Effluent Flotation Systems

Water Type	Concentrate			Tail		% Recovery	
	Wt. %	% Cu	% Mo	% Cu	% Mo	Cu	Mo
Standard	6.8	6.52	0.120	0.055	0.0035	89.7 ± 1.2	71.7 ± 1.0
Sewage	8.5	5.09	0.078	0.069	0.0058	87.3 ± 0.9	55.5 ± 1.7

addition of frother) that has little mineral carrying capability and is difficult to control. The initial froth in the standard test is smaller in volume, and is heavily laden with a coating of bright, brassy chalcopyrite. As the standard test proceeds and the initial froth is removed, it is replaced by a froth of relatively uniform bubble size of smaller diameter than the initial bubbles. Occasionally, the larger bubbles reappear. The frequency of occurrence of the larger bubbles, the size of the smaller uniform bubbles, and the thickness and brightness of the mineral coating all diminish as the test proceeds. As the sewage effluent test proceeds and the initial froth is removed, the same gradual decrease in bubble size and mineral coating occurs. However, toward the end of the test the bubbles in the sewage effluent test give a wet, sudsy appearance and seem to contain more slime particles than the standard froth at the same point.

The first sections of this investigation, in addition to establishing a standard flotation test procedure, served to define the effects that secondary treated sewage effluent has on the flotation process when it is substituted for standard water. First, sewage effluent causes a substantial decrease in molybdenum recovery. It also causes a small but significant decrease in copper recovery. Finally, sewage effluent creates a voluminous froth, even in the absence of frother, that is difficult to control and has little mineral carrying ability. The remainder of this investigation was devoted to determining changes in the reagent schedule to compensate for the effect of sewage effluent and to examining methods of treating sewage effluent to make it more acceptable for flotation.

Dilution of Sewage Effluent with Demineralized Water

In the event that sewage effluent were utilized on a large scale by a copper concentrator, eventually the entire water inventory would be sewage effluent. It is likely, however, that the detrimental constituents of the effluent would be removed from the system by the flotation process. Therefore, the recycled water supply might consist of acceptable water and only sewage effluent added for makeup would create a problem. Consequently, the detrimental effects of sewage effluent under these conditions might not be as severe as those encountered with complete replacement with sewage effluent as practiced in tests previously reported. This possibility was evaluated by performing flotation tests using sewage effluent diluted with demineralized water.

Figure 5 shows the effects on copper and molybdenum recovery of diluting sewage effluent with standard demineralized water. Dilutions were made by mixing measured quantities of the two water types in a plastic container until a well blended solution was obtained. The data indicate a gradual, almost linear, increase in recovery for both copper and molybdenum with increasing percentages of standard demineralized water. In the case of molybdenum, however, small additions of standard water appeared to cause a disproportionate increase in recovery. In general, the improvement in recovery appears to be attributable to simple dilution of the deleterious constituents contained in sewage effluent.

Dilution of Sewage Effluent with Process Tailings Slurry

Process tailings discharged from a flotation concentrator might be used to remove some of the deleterious contaminants contained in sewage effluent. By mixing sewage effluent with process tailings slurry, the relatively high surface area of the ground ore particles might adsorb some of the undesirable contaminants contained in the effluent prior to its contact with fresh ore, and thus eliminate some of the detrimental effects that sewage effluent has on flotation recovery. A test series was conducted to determine the merits of this proposal. The tests involved establishing a reference curve using sewage effluent diluted with various quantities of clear process water, and then combining sewage effluent with samples of process tailings slurry and comparing the results thus obtained with the reference curve at the appropriate dilution. Samples used for these experiments were obtained from the Cyprus Pima concentrator. Tailings thickener overflow water was used where required, and tailings thickener underflow slurry was used where dilutions with slurry were required. Figure 6 shows the effects on copper and molybdenum recovery of diluting sewage effluent with clear process water

Figure 5. The effect of diluting sewage effluent with demineralized water.

Figure 6. The effect of diluting sewage effluent with Cyprus Pima process water and process slurry.

Table 4

South Tahoe Public Utility District
Estimated Overall Plant Efficiency

Quality Parameter	Raw Waste Water Influent	Activated Sludge Effluent	Reclamation Plant: Separation Bed Effluent	Reclamation Plant: Chlorinated Carbon Column Effluent
BOD, mg/1	200-400	20-100	1	1
COD, mg/1	400-600	80-160	30-60	3-16
Suspended solids, mg/1	160-350	5- 20	0.5	0.5
Turbidity, units	50-150	20- 60	0.5	0.5
Phosphate, mg/1	15- 35	10- 30	0.4-2.0	0.2-1.0
Chlorine Demand, mg/1	Over 50	10- 50	5-10	1-3
Odor	Odor	Odor	Odor	Odorless

and process slurry. The addition of process tailings slurry to sewage effluent had no beneficial effect on flotation recovery, and the deleterious constituents contained in sewage effluent apparently do not adsorb on the surface of ground ore particles to any measurable extent. Furthermore, aging the slurry-sewage effluent solution for 2 days had no effect on water quality in terms of flotation response.

Activated Carbon Treatment of Sewage Effluent

A method sometimes employed to improve the quality of industrial and municipal waste waters is treatment with activated carbon. Granular activated carbon treatment of large quantities of waste water began in the early 1960s (Hager, 1974). The development of granular activated carbon with the capability of regeneration and reuse made adsorption an economic alternative for removal of dissolved organics and other contaminants from waste water. At Lake Tahoe, California, the South Tahoe Public Utility District uses activated carbon for tertiary treatment of more than 2.5 mgd of activated sludge effluent prior to discharge to the environment (McDonald, 1965). The water discharged from the plant has been characterized as being colorless, odorless, and crystal clear. The water reclamation plant's estimated overall plant efficiency is summarized in Table 4 (McDonald, 1965).

A laboratory activated carbon column was constructed and operated to determine the effect of activated carbon treatment of sewage effluent on flotation recovery. Table 5 summarizes the column operating conditions. Sewage effluent was pumped upward through the column at a controlled rate with a contact time of 2 minutes. No attempt was made to maximize the efficiency of the column and no chemical analysis of column influent or effluent was performed.

Figures 7 and 8 show the effect on copper and molybdenum recovery of treating sewage effluent with activated carbon. The results indicate a significant increase for both copper and molybdenum recovery when sewage effluent is treated with granular activated carbon. Further improvements in sewage effluent quality may be obtained with longer carbon contact times. Indeed, mining company personnel have indicated that they have generated water from sewage effluent using activated carbon treatment that is of a quality equal to their standard process water in terms of flotation response (Khan, 1975).

Table 5

Activated Carbon Column Operating Conditions

Carbon Description	6X16 mesh Pittsburgh Activated Carbon

		Sodium and Potassium	116

appear to be some minor residual frothing characteristics that are associated with untreated sewage effluent. A longer carbon contact time might eliminate most of the detrimental frothing characteristics associated with sewage effluent.

Ion Exchange Removal of Contaminants in Sewage Effluent

The number and variety of contaminants contained in sewage effluent is large. This fact is evident from viewing the typical sewage effluent analyses presented in Table 6 for plant Number 3 of the City of Tucson Roger Road treatment facility for fiscal year 1974-75 (Trueblood, 1975).

In an attempt to determine whether the deleterious constituent or constituents present in sewage effluent are cations, anions, or neutral molecules, a series of ion exchange tests were performed on sewage effluent samples. Amberlite 200, a cationic exchange resin with a sulfonic acid functional group, was loaded in the acid form and used to exchange cations in sewage effluent. Sewage effluent samples were first filtered through Whatman No. 50 filter paper, and then agitated with 250 milliliters of resin for 30 minutes in a 4 liter pyrex beaker. After cation exchange, the pH of the resulting solution was adjusted from 2.8 to 7.5 with sodium hydroxide. The water thus generated was then used in laboratory flotation tests to determine the effect of cation removal on flotation recovery. In a similar procedure, anions were removed from filtered sewage effluent using Amberlite IRA 900, an anion exchange resin with a quaternary ammonium functional group loaded in the hydroxide form. The pH of the anion exchanged sewage effluent was adjusted from 11.5 to 7.6 with sulfuric acid and the resulting effluent solution was used in laboratory flotation tests. Exchange of both cations and anions was accomplished by first exchanging cations with Amberlite 200, and then exchanging anions with Amberlite IRA 900. The pH of the resulting solution was adjusted from 10.7 to 6.7 with sulfuric acid. Table 7 shows a comparative metallurgical summary of the flotation results obtained with water generated by the foregoing procedures. Flotation results of ion exchanged sewage effluent are compared with standard water, as received sewage effluent, and filtered sewage effluent.

Table 7 illustrates that a significant increase in both copper and molybdenum recovery can be achieved by removing the anions from sewage effluent. Whether the deleterious ionic species is a simple inorganic ion, a more complex organic derivative, or a combination of both has not been determined.

Foam Fractionation of Sewage Effluent

Foam fractionation has been employed in a number of engineering applications (Kobe and McKetta, 1962 and Schoen, 1962). In one instance, alkyl benzene sulfonate and other organics analyzed as chemical oxygen demand have been removed from secondary sewage effluent (Rubin, 1963). The process of foam fractionation utilized the tendency of surfactants to accumulate at the air-aqueous interfaces formed when bubbles are generated in a liquid. This process deals with a two phase system: that is, a gas and a liquid, in contrast to froth flotation which deals with a three phase system involving one or more solid constituents.

A series of flotation tests utilizing foam fractionated sewage effluent was conducted to determine the effect on flotation of foam fractionation. Sewage

Table 8

Comparative Metallurgical Summary for
Foam Fractionation Test Series

Water	Concentrate			Tails		% Recovery	
	Wt. %	% Cu	% Mo	% Cu	% Mo	Cu	Mo
Standard Water	6.8	6.52	0.120	0.055	0.0035	89.7	71.7
Sewage Effluent	7.4	5.86	0.093	0.065	0.0060	87.8	55.4
Foam Fractionated Sewage Effluent	7.2	5.96	0.098	0.060	0.0060	88.4	55.8

effluent was foam fractionated for 10 minutes in a laboratory flotation cell without frother. Table 8 shows a comparison of flotation results obtained for standard water, sewage effluent and foam fractionated sewage effluent.

The results indicate that foam fractionation did not improve the quality of sewage effluent in terms of flotation metal recovery. There was, however, a noticeable improvement of frothing qualities. The voluminous, unmanageable froth associated with sewage effluent appeared to be significantly reduced. Foam fractionation could be employed as one approach to froth control when utilizing sewage effluent.

Substitution of an Alternate Collector for Potassium Amyl Xanthate

A collector frequently employed in copper and molybdenum flotation is the allyl ester of amyl xanthate (S-3302). This water insoluble, oily collector is sometimes used in combination with a xanthate, fuel oil, and a frother, to give optimum copper and molybdenum rougher flotation results. Because this type of collector is also in wide use in industry, a series of flotation tests were conducted using the same procedure previously described with the exception that 0.04 pound per ton of S-3302 was added to the grinding mill in place of 0.04 pound per ton of Z-6. Figures 9 and 10 show the effect on copper and molybdenum recovery, respectively, of substituting S-3302 for Z-6 in demineralized water and sewage effluent flotation systems. Figure 9 indicates that copper recovery with S-3302 is less sensitive to pH change than is Z-6 in both standard demineralized water and sewage effluent. Above a pH of about 9 to 9.5, copper recovery is adversely affected by the substitution of S-3302 for Z-6 in both standard water and sewage effluent systems. Figure 10, on the other hand, shows that molybdenum recovery is increased dramatically over the entire pH range studied for both demineralized water and sewage effluent systems. In fact, the recovery versus pH curve for S-3302 in the sewage effluent system lies almost directly on the recovery versus pH curve for Z-6 in standard demineralized water. Figure 11 shows a comparison of the percent of iron contained in the rougher concentrate for Z-6 and S-3302 in demineralized water. Since S-3302 is already widely used by industry, the results of this test series are of fundamental interest.

Fuel Oil in Combination with Potassium Amyl Xanthate

A study of this nature could not be complete without determining the effect of fuel oil addition on molybdenum recovery in both the sewage effluent and demineralized water flotation systems. Fuel oil is almost universally used in commercial molybdenum flotation as a molybdenum promoter. Table 9 summarizes the results of a test series (using Z-6 as the collector) to determine the effect of fuel oil addition on copper and molybdenum recovery.

Figure 9. Comparison of copper recovery vs. pH for demineralized water (D. W.) and sewage effluent (S. E.) using Z-6 and 3302 as collectors.

Figure 10. Comparison of molybdenum recovery vs. pH for demineralized water (D. W.) and sewage effluent (S. E.) using Z-6 and 3302 as collectors.

Table 9

Effect of Fuel Oil Addition on Copper and Molybdenum Recovery in Demineralized Water and Sewage Effluent Flotation Systems

Fuel Oil, Lb/Ton	Water Type: Demineralized % Recovery Cu	Demineralized % Recovery Mo	Sewage Effluent % Recovery Cu	Sewage Effluent % Recovery Mo
0	89.2	68.7	89.1	52.8
0.025	89.7	70.8	90.3	59.5
0.05	90.0	75.7	88.8	63.1
0.10	90.0	78.4	89.0	68.3
0.20	91.2	81.0	90.2	73.9
0.40	--	--	89.9	69.3

This table clearly indicates the beneficial effect of fuel oil addition on molybdenum flotation in both standard water and sewage effluent systems. The magnitude of molybdenum losses attributed to sewage effluent are substantially reduced by the addition of fuel oil to the system. However, the molybdenum losses attributable to sewage effluent are still significant. There appears to be no appreciable effect on copper recovery by the addition of fuel oil to the systems studied.

A Multicomponent Reagent Schedule

Most concentrators in the vicinity of Tucson employ a flotation reagent combination consisting of a primary collector, a supplemental collector, fuel oil, and a frother for the recovery of copper and molybdenum sulfides. A single "optimum" reagent combination that works equally well for all copper-molybdenum ores does not exist, and consequently, reagent schedules differ from concentrator to concentrator. The metallurgical staff for a particular operation may have invested years developing and refining a reagent combination that satisfies their operating requirements most of the time. With the foregoing in mind, an attempt was made to establish the effect of sewage effluent on copper and molybdenum recovery using a multicomponent reagent system. The emphasis in this test series was placed on reducing the large detrimental effect that sewage effluent has on molybdenum recovery.

Table 10

Multicomponent Reagent Schedule

Reagent	Quantity, Lb / Ton
Z-6	0.013
S-3302	0.027
Fuel Oil	0.025
MIBC	0.03

Previous testwork in which S-3302 was substituted for Z-6 established that a very significant increase in molybdenum recovery could be obtained by using S-3302. Since this reagent is widely used by the copper industry, it was chosen as the supplemental collector.

In the development of the multicomponent reagent schedule, the effect of S-3302 addition level on flotation response was determined. Figure 12 shows the results obtained from a test series devoted to this end. The most significant features of this figure are the large increases in molybdenum recovery accompanied by corresponding decreases in copper recovery.

To determine the interaction of Z-6 and S-3302 when both are used simultaneously as collectors, a series of tests using various combinations of these flotation reagents was conducted. The results of this series are shown in Figure 13. All tests were carried out in standard water at a pH of 11.5, with 0.04 pound per ton total collector addition, using MIBC as the frothing agent at a level of 0.04 pound per ton. Since the objective of this section of the study was to increase molybdenum recovery, a ratio of S-3302 to Z-6 of 2:1 was chosen as an acceptable collector combination. This choice was obviously a compromise between the desired higher molybdenum recovery and reduced, but reasonable, copper recovery.

The reagent schedule listed in Table 10 was selected on the basis of the cumulative experience gained in this investigation with the emphasis on minimizing molybdenum losses.

Table 11

The Effect of Sewage Effluent on Copper and Molybdenum Recovery in a Simple Reagent System and a Complex Multicomponent Reagent System

Water Type	% Recovery: Simple System Cu	Simple System Mo	Cu	Mo
Standard	89.7 ± 1.2	71.7 ± 1.0	83.1 ± 0.6	77.3 ± 1.2
Sewage	87.3 ± 0.9	55.5 ± 1.7	80.1 ± 1.0	71.9 ± 1.3

Figure 11. Comparison of percent iron in rougher concentrate vs. pH for demineralized water using Z-6 and 3302 as collectors.

Figure 12. Copper and Molybdenum recovery vs. collector addition in demineralized water.

Figure 13. Copper and molybdenum recovery as a function of combined Z-6 and S-3302 at a total collector addition of 0.04 lb/Ton.

Table 11 shows a comparison of recoveries at the 95 percent confidence level obtained in standard water and sewage effluent systems for the simple Z-6 reagent schedule and the multicomponent reagent schedule described above. All tests were conducted at a pH of 11.5. Although the multicomponent reagent schedule is effective in improving molybdenum recovery, the loss of molybdenum in the sewage effluent system remains significant and the reduction in copper recovery is unacceptable.

CONCLUSIONS

The conclusions drawn from this study are intended to serve as a guideline and reference from which future investigations can proceed. They are not intended to serve as a definitive prediction of operating results for commercial scale utilization of City of Tucson sewage effluent in mineral processing. The following conclusions can be drawn from the experimental results generated in this investigation.

1. Secondary treated sewage effluent caused a small but measurable decrease in copper recovery and a substantially larger decrease in molybdenum recovery when used in place of demineralized water. In the simple reagent system used as a basis for this study, sewage effluent caused a reduction in recovery on the order of 2.4 and 16.2 percentage units respectively for copper and molybdenum.
2. Secondary treated sewage effluent creates a voluminous froth, in the absence of frother, that is difficult to control and has a reduced capacity to carry minerals.
3. Dilution of sewage effluent with demineralized water results in a proportionate reduction of the detrimental effects associated with the effluent.
4. Combining process tailings slurry with sewage effluent has no beneficial effect on sewage effluent quality in terms of flotation metal recovery. Deleterious constituents contained in sewage effluent are apparently not adsorbed on particles of ground ore.
5. Tertiary treatment of sewage effluent by activated carbon results in a significant improvement in water quality measured in terms of flotation metal recovery. Detrimental foaming characteristics of sewage effluent are significantly reduced by activated carbon treatment.
6. Ion exchange removal of anions contained in sewage effluent results in a significant improvement in water quality in terms of both copper and molybdenum recovery. In addition, the foaming attributed to sewage effluent is significantly reduced. This result indicates that the species detrimental to metal recovery are anions.
7. Foam fractionation does not improve the quality of sewage effluent in terms of flotation metal recovery. There is, however, an improvement in the deleterious frothing characteristics associated with the effluent.
8. Use of a multicomponent reagent schedule results in a significant improvement in molybdenum recovery using both demineralized water and sewage effluent. However, this reagent system causes an unacceptable loss in copper recovery.

ACKNOWLEDGMENTS

Water chemistry effects in the flotation of sulphide ores—a review and discussion for molybdenite

Maurice R. Hoover Min. Eng., M.S., Ph.D.
Exxon Research & Engineering Co., Minerals Division, Florham Park, New Jersey, U.S.A.

Synopsis

The steadily rising consumption of water and an increased usage of recycled mill waters presently constitute important problems for the mineral industries throughout the world. The detrimental effect of waste water impurities in the flotation recovery of sulphide ores is presently recognized. The objective of the present study is to bring together the information on water chemistry effects as it relates to the flotation of sulphide ores. Molybdenite has been selected for illustrative purposes. From the published literature the effect of colloid: inorganic cations, inorganic anions and organic species on the floatability of molybdenite is reviewed. The experimental data provide a clear picture of the effect of cations and colloidal material on the molybdenite surface. In general, we can postulate that inorganic cations are not detrimental for MoS_2 flotation. Precipitated colloidal hydroxides (especially aluminium and iron) have a strong depressant action on MoS_2 flotation, due mainly to a 'slime coating' phenomenon. The deleterious effect of inorganic anionic species is experimentally known, but very limited specific information is available. A method to overcome the detrimental effects of 'slime coatings' is discussed, and recommendations are made for systematic research in the area of water chemistry effects in the flotation of sulphide ores.

In most parts of the world, because of increasing energy problems and the resurgence in the care for the environment in which we live, a continuous drive towards a more efficient recovery of minerals and decreasing or eliminating the discharge of waste water from minerals processing plants into streams or other waters where it can become environmentally harmful has been mounted. This has resulted in increased usage of recycled mill waters and other waste water products for the processing of ores.

The effect of water impurities on the flotation recovery of sulphides has been under investigation by several researchers since the introduction of the flotation process. Published information has been compiled since the late 1930s, when the discovery was made that flotation in fresh water and recycled mill water often produced different recoveries. We generally accept now that recycle mill water actually gives lower recoveries.

Published data are highly divergent in their interpretation of the causes for the loss in recovery attributed to 'bad water'. The objectives of this paper are to bring together information on water chemistry effects as it relates to flotation of sulphide ores with specific collector systems and pulp mineralogy in various stages of the concentration process and to establish the basis for a systematic investigation. The data presented in this publication are derived from published scientific literature and from the personal experience of the author. Since it was not possible to include all the information for all the commercially important sulphide minerals, one mineral—molybdenite—was selected for illustrative purposes.

Background

Occurrence

The only molybdenum mineral of commercial importance is molybdenite (MoS_2), although small deposits of molybdenum-bearing minerals, such as wulfenite, powellite and ferrimolybdite, occur throughout the world. Molybdenite occurs in four generic deposits. These include: (1) porphyry or disseminated deposits, including stockworks and breccia pipes, in which metallic sulphides are dispersed through relatively large volumes of altered and fractured rock (examples include Climax, Urad and Henderson, U.S.A.); (2) contact-metamorphic zones and tactite bodies of silicated limestone adjacent to intrusive granite rocks (examples include most of the western United States porphyry copper–molybdenum deposits and the Pine Creek tungsten–molybdenum deposit in California); (3) quartz veins and stringers (an example is Questa, U.S.A.); and (4) pegmatites and aplite dykes (examples are Val d'Or and Preissac, Canada).

Most of the world's molybdenum reserves coincide with copper reserves and are located in the western mountain regions of North and South America, extending from Alaska and British Columbia through the United States, Mexico and Central America to the Andes Mountains of Chile. These regions roughly border the western margin of the Pacific Basin and are regarded as most promising for the discovery of additional reserves in the future. In the U.S.A. 70% of reserves occurs in large porphyry or disseminated deposits, such as Climax, Henderson and Questa, in which molybdenum is the major resource. The remaining 30% is contained in porphyry copper deposits and is recovered as a by-product of copper mining. In Canada 30% is contained in a single primary deposit (Endako), 70% being associated with copper–molybdenum porphyry deposits in British Columbia. On the other hand, in Central and South America and in the U.S.S.R. molybdenum is primarily contained in several large copper porphyry deposits.

Processing

Most molybdenite-bearing porphyries contain copper, iron, lead, zinc and other minor quantities of complex sulphide minerals that require rejection during processing to produce a final marketable molybdenite concentrate.

The general flowsheet for a primary ore consists of rougher flotation at a coarse primary grind followed by multiple-stage regrinding and cleaner flotation of a relatively low-grade rougher concentrate to produce a final concentrate of specification grade. For by-product molybdenite from a copper–molybdenum porphyry the general flowsheet consists of bulk flotation of molybdenite and copper sulphides followed by selective flotation of molybdenite in repeated countercurrent flotation circuits to depress the copper and iron sulphide

minerals by addition or pretreatment with specific reagents.

Water chemistry effects in molybdenite processing

In a recent publication[1] the results of tests to determine which constituents of waste water, such as secondary treated sewage effluent, were detrimental to the flotation of molybdenite and copper sulphides were reported. These tests included treating the waste water in Barnstead cartridges to remove specific groups of ions and assessment of the effect on the flotation metallurgy of the treated water.

Some of the experimental results obtained from the flotation tests are presented in Figs. 1 and 2. These results are summarized below.

(*a*) The use of sewage effluent caused a decrease in recovery of 16.2% for MoS_2 and 2.4% for copper sulphides.

(*b*) Dilution of the sewage effluent with distilled water resulted in a proportionate decrease in the detrimental effects associated with the use of waste water effluent.

(*c*) Removal of cations from the sewage effluent resulted in a slight improvement of the recoveries.

(*d*) Removal of anions from the sewage effluent resulted in the most significant improvement in copper and molybdenum recovery.

(*e*) Foam fractionation to remove surface-active material did not improve the quality of sewage effluent, and hence the recoveries were at the same level as that of untreated sewage effluent.

Fig. 1 Molybdenite recovery versus pH for demineralized water (D.W.) and sewage effluent (S.E.). After Fisher and Rudy[1]

(*f*) Tertiary treatment of the sewage effluent by activated carbon resulted in a significant improvement in water quality measured in terms of recovery of metals,

Fig. 2 Molybdenite recovery versus pH for demineralized water (D.W.), sewage effluent (S.E.) and activated carbon (A.C.). After Fisher and Rudy[1]

but not to the level achieved by removal of anionic species.

Similar results have been reported by many concentrators that have attempted to recycle process water, but published data on the effects of recycle water are scarce. Essentially, all the known data demonstrate a strong influence of soluble water constituents on the recovery of molybdenite and provide the basis for a more detailed review and discussion.

This paper includes a literature review on the mechanism of interaction between water components, cations, anions, colloids and organic species, and molybdenite surface, followed by a detailed discussion on ways to overcome detrimental effects of water components. Also included are recommendations for research programmes to gain a full understanding of water chemistry effects on sulphide minerals flotation.

Review of published literature

Interaction of inorganic and organic ions and colloids with molybdenite

Effect of hydrogen ion (pH)

Arbiter and co-workers[2] found that the relationships (1) zeta-potential versus pH in the absence of ionic species besides pH modifiers and (2) flotation recovery versus pH do not correlate well for molybdenite. On the other hand, Chander and Fuerstenau[3,4] found a definite qualitative correlation between zeta-potential and Hallimond tube flotation for molybdenite. As shown in Fig. 3, the higher the MoS_2 zeta-potential, the lower the MoS_2 flotation recovery. A similar correlation to that reported by Chander and Fuerstenau has been

Fig. 3 Zeta-potential and flotation recovery of leached molybdenite as a function of pH. After Chander and Fuerstenau[3,6]

observed and reported by Hoover and Malhotra.[8] Chander pointed out that theoretical calculations with DLVO theory[9] predict that no flotation can occur unless the potentials are about −0.1 V, assuming the potential of an air bubble to be −0.055 V.[7] In practice, however, MoS_2 flotation takes place at much lower potentials. To explain the experimental results, several investigators[3,4] have postulated that the faces and edges of the anisotropic molybdenite crystals have different contributions to the measured zeta-potential, the zeta-potential of the faces being small (probably about −0.01 V) and the potential at the edges being large. Thus, edges control the observed zeta-potential. Chander and Fuerstenau[3,6] postulated the existence of charged surface of thiomolybdate species to explain the observations. The following equilibrium reaction, assumed to occur mainly on the edges of the molybdenite particles, might explain the pH-dependence of the zeta-potential:

$$[MoS_XO_Y]^{-n} + H^+ = [MoS_XO_YH]^{-n+1}$$

A special case for $X = 0$, $Y = 4$ and $n = 2$ is

$$MoO_4^{-2}\ (\text{surface}) + H^+\ (\text{solution}) = HMoO_4^-\ (\text{surface})$$

This reaction in homogeneous solution has a pK of 5.95.[4]

The presence of negatively charged surface ions explains the negative zeta-potential of molybdenite, and the equilibrium between these species and hydrogen ions explains the pH-dependence of the zeta-potential as shown in Figs. 4 and 5. The zeta-potentials of Chander and Fuerstenau for samples 1 and 2 and the reported values[2,8] support this hypothesis. Sample 1, which was obtained by crushing molybdenite crystals in a roll crusher, has more uniform surface in comparison with the particles in sample 2, which were obtained by grinding molybdenite in a jet mill.[8] The data reported by Hoover and Malhotra[8] and also by Arbiter and co-workers[2] represent coarser particle-size ball-mill products and are presented in Fig. 4 according to their edges/faces ratio. Higher edges/faces ratios have a higher density of charged surface species and, as a result, their zeta-potential is always more negative. Fig. 5 shows[9] the relationship between the zeta-potential of MoS_2 and pH, and the zero point of charge (zpc) of MoS_2 is about 2.4. In this study slightly higher potentials were observed above the zpc in the presence of H_2SO_4 than in the presence of HCl. When NaOH and Na_2CO_3 were used for pH adjustment the zeta-potential became quite negative (about −60 mV at pH 10) and then turned less negative above pH 10, probably because of the adsorption of Na^+ at these higher pH values.

Additional evidence on qualitative correlation between zeta-potential and flotation response for molybdenite will be presented later.

Effect of calcium ion (Ca^{++})

The effect of Ca^{++} on the floatability of molybdenite is probably the best understood and most thoroughly

Fig. 4 Zeta-potential of molybdenite in water as a function of pH

Fig. 5 Relationship between zeta-potential of MoS_2 and pH with various reagents for pH adjustment. After Fuerstenau[9]

studied. Chander and Fuerstenau[4,8] studied the influence of Ca^{++} on zeta-potential and the flotation of molybdenite. The zeta-potentials of leached molybdenite in the presence of Ca^{++} are shown in Fig. 6.[8] The zeta-potentials became less negative with an increase in Ca^{++} concentration, but the shape of the zeta-potential–pH curve remained unchanged. As was suggested by Chander and Fuerstenau,[3,8] $HMoO_4^-$ and MoO_4^{--} ions are strongly specifically adsorbed on molybdenite and thus may serve as potential-controlling surface species. In

The zeta-potential of molybdenite as a function of Ca^{++} concentration is shown in Fig. 7. At Ca^{++} concentrations less than 10^{-3} M, virtually no change occurs in the zeta-potential, but the potential becomes less negative in the presence of Ca^{++} than in the presence of K^+. At larger concentrations of KCl no indication exists of a change in the sign of the zeta-potential. On the other hand, the zeta-potential becomes positive at large Ca^{++} concentration because of the specific adsorption of Ca^{++}. The concentration at which

Fig. 6 Zeta-potential of leached molybdenite as a function of pH in presence of calcium ions. After Chander and Fuerstenau[3,8]

the presence of Ca^{++} the surface charge may well change because of the reaction

$$MoO_4^{--}\text{ (surface)} + Ca^{++}\text{ (solution)} \rightleftharpoons CaMoO_4\text{ (surface)}$$

The corresponding reaction in homogeneous solution has $pK = 7.38$.[10] Adsorbed Ca^{++} neutralize an equal amount of MoO_4^{--} ions, thus decreasing the surface charge and the zeta-potential.

the zeta-potential reverses sign increases with an increase in the pH of the solution. This is an expected change because at higher pH all the surface species are present as MoO_4^{--} ions, whereas at lower pH values some surface species are $HMoO_4^-$ ions. The concentration of Ca^{++} required for reversal of the zeta-potential is designated as the pzr, i.e. the point of zeta reversal. The decrease in zeta-potential on further increase in Ca^{++} at pH 3.8

Fig. 7. Zeta-potential of leached molybdenite as a function of salt concentration. After Chander and Fuerstenau[3,4]

probably results from the competition between compression of the double layer and specific adsorption of the Ca^{++} on the crystal faces.

Lenkovskaya and Stepanov[11] measured the adsorption of calcium on molybdenite by using a radioactive tracer technique (^{45}Ca isotope). Their data (Fig. 8) indicate that adsorption of Ca^{++} on molybdenite increases with pH and concentration of free $Ca(OH)_2$ in the system.

Fig. 8. Adsorption of calcium ions as a function of free $Ca(OH)_2$ content in slurry (mg/l) and pH (pH adjusted with H_2SO_4 and NaOH). After Lenkovskaya and Stepanov[11]

The flotation recovery curves for molybdenite as a function of calcium chloride concentration as reported by Chander and Fuersteanu[3,4,8] in Fig. 9 show good accord with the zeta-potential measurements. This is additional supporting evidence to the qualitative observation of correspondence between zeta-potential and flotation response of molybdenite. Flotation recovery is maximum at pzr, as shown by the dotted vertical line in Fig. 9. The flotation recovery first increases with increase in Ca^{++} concentration; this recovery increase may be attributed to the decrease in electrical layer repulsion between the particle and the bubble. At higher Ca^{++} concentrations than those which correspond to maximum flotation recovery the adsorption of Ca^{++} may make the faces more hydrophilic because of an increase in the dehydration energy or the corresponding disjoining pressure; consequently, floatability is decreased. Also, Lenkovskaya and Stepanov[11] found that as the pH of the medium increases, the floatability of molybdenite decreases for all types of pH modifiers, with the possible exception of Na_2CO_3. As is shown in Fig. 10, frother and xanthate were used in this case. Xanthate, however, has been proved[22] to be non-surface-active on MoS_2; consequently, the experimental results presented in this review are compatible.

The results of Chander and Fuerstenau[3,4,8] have been corroborated by Malhotra and co-workers[12] with Climax Molybdenum Co. ore. These data showed that Ca^{++} is beneficial for flotation of MoS_2 up to a certain point, above which it becomes detrimental to MoS_2 recovery.

Effect of ferric (Fe^{+3}) and ferrous (Fe^{+2}) ions

In general milling practice 40–90% of the steel consumption is due to electrochemical corrosion[13] according to the reaction

$$Fe^0 + 2H^+ \rightleftharpoons Fe^{+2} + H_2$$

In a laboratory study[13] a major difference has been detected by grinding with mild steel, stainless steel or porcelain media. The concentration of Fe^{++} was ten times greater in pulps ground with mild steel versus stainless steel and 25 times more by grinding with mild steel than with porcelain. In commercial plants Fe^{++} oxidizes and precipitates as ferric hydroxide, as indicated by a very low Fe^{++} concentration in the discharge of the ball-mill grinding circuits[14] according to the reactions

$$Fe^{+2} + \tfrac{1}{4}O_2 + H^+ = Fe^{+3} + \tfrac{1}{2}H_2O$$
$$Fe^{+3} + 3H_2O = Fe(OH)_3 + 3H^+$$

In the sealed laboratory mills sufficient oxygen may not be available for this reaction to go to completion. Thus, the Fe^{+2} oxidation reaction and the resulting $Fe(OH)_3$ precipitate represent a plant condition that is not easily reproduced in the laboratory.

Lenkovskaya and Stepanov,[11] who used 200 different samples, have shown (Fig. 11) that Fe^{+3}, present as finely divided $Fe(OH)_3$ particles (colloids), has the greatest negative effect on the floatability of molybdenite. These investigators studied the effect of several inorganic salts on the floatability of pure molybdenite at pH 7.5 ± 0.3, which corresponds, according to the authors, to the optimum flotation pH for the treatment of primary molybdenite ores, and in a strongly alkaline medium at pH 11.3 ± 0.2, which corresponds, again according to the same investigators, to the optimum pH in the upgrading of rougher molybdenite concentrates. Also, the effect of salts on a molybdenite concentrate (54% Mo) produced from a

copper sulphide–MoS_2 separation process with Na_2S was studied at pH 10.3 ± 0.3. This pH corresponds to the optimum pH for the separation of a bulk copper–molybdenite concentrate. In these experiments the inorganic salt was added before the pH modifier.

Fig. 12. Effect of soluble salts on floatability of molybdenite by xanthate (25 mg/l) at pH 7.5 ± 0.3. After Lenkovskaya and Stepanov[11]

The results on the effect of inorganic salts on the floatability of MoS_2 at pH 7.5 ± 0.3 shown in Fig. 12 demonstrate that the salts of trivalent iron have a highly depressant effect on the floatability of molybdenite. The effect of the same inorganic salts at pH 11.3 ± 0.2 is given in Fig. 13, which shows the adverse effect of the ferric and ferrous iron salts; the effect of these inorganic salts on molybdenite concentrate at pH 10 ± 0.3 gave the same results as those obtained at pH 11.3 ± 0.2.

Fig. 13. Effect of soluble salts on floatability of molybdenite by xanthate (25 mg/l) at pH 11.3 ± 0.2, adjusted with $Ca(OH)_2$. Soluble salts formulas represent chemical compound added to system—not ions in solution. After Lenkovskaya and Stepanov[11]

To identify the effect of the individual inorganic salts that can be used as pH modifiers additional tests were carried out by Lenkovskaya and Stepanov[11] over a wide range of pH values with various alkaline reagents. The experimental results presented in Fig. 8 show that if trivalent iron salts are present in the system, the adsorption of calcium ion on molybdenite is substantially enhanced. Hence, the effect of Fe^{+3} on MoS_2 floatability was tested over a wide range of pH values in the presence of $Ca(OH)_2$ and NaOH (Fig. 14). At 5.16×10^{-3} mole/l $FeCl_3$ concentration the data in Fig. 14 show that, at pH > 10.5 if trivalent iron is present, an abrupt decrease occurs in the floatability of molybdenite, particularly in the presence of lime.

In addition, Lenkovskaya and Stepanov[11] determined iron adsorption on MoS_2 with 'tagged' ^{59}Fe at a constant Fe^{3+} concentration (5.16×10^{-3} mole/l) over a wide pH range (these data are also shown in Fig. 14). Maximum iron adsorption is observed in the pH 10–12 range in the presence of lime and corresponds to the pH range of formation of visible precipitates. Above pH 12 the adsorption of iron decreases, and therefore the floatability of MoS_2 is restored. This pH range corresponds to the absence of visible iron precipitates. An important observation of this study is the recognition of the fact that in the pH 7–8 range the depressant effect of Fe^{+3} is minimal or almost absent. This observation has definite practical implications in the flotation of MoS_2 from primary Mo ores.

Effect of other inorganic cations and colloids

The influence of other cations—Al^{+3}, Cu^{+2}, Cu and Na^{+}—was also investigated by Lenkovskaya and Stepanov,[11] these results being presented in Figs. 12 and 13. At pH 7.5 ± 0.3 molybdenite floatability was enhanced by Cu^{+2}, whereas Al^{+3} had a depressant action. The ions of Cu^{+} and Na^{+} exhibited no effect on MoS_2 flotation. At pH 11.3 ± 0.2, except for Fe^{+3}, no ions were detrimental to MoS_2 flotation.

The depressant effect of Al^{+3} was tested over a wide range of pH values in the presence of $Ca(OH)_2$ and NaOH (Fig. 15). The aluminium salt was kept at

Fig. 14. Effect of Fe^{+3} salts as a function of pH on floatability of MoS_2 with xanthate (25 mg/l) (concentration of $FeCl_3$ 5.16×10^{-3} mole/l. After Lenkovskaya and Stepanov[11]

Fig. 15. Effect of Al^{+3} salts as a function of pH on floatability of molybdenite with xanthate (25 mg/l). Concentration of $Al(NO_3)_3$ 5.16×10^{-3} mole/l. After Lenkovskaya and Stepanov[11]

5.16×10^{-3} mole/l, since this concentration was (Figs. 12 and 13) the same as for the Fe^{+3} case at which maximum depression of MoS_2 occurs. The experimental results of Fig. 15 show that Al^{+++} aluminium renders the greatest depressant effect on MoS_2 in the pH 4.5–8 range and, in addition, depresses molybdenite more strongly in the presence of NaOH. Again, attention should be drawn to the fact that an intensification of the depressant action of the inorganic salts coincides with the pH range in which visible precipitates form. The experimental observation is especially marked for aluminium salts, the depressant effect of which becomes stronger in the pH range that corresponds to the formation of amphoteric aluminium hydroxides.

Effect of inorganic anions

Very little published information is available on the effect of inorganic anions on molybdenite flotation. Chander and Fuerstenau,[4,6] to obtain a better understanding of the role of molybdate ions in the MoS_2 surface processes in terms of both the zeta-potential and the flotation of molybdenite, have reported data on leached molybdenite in the presence and absence of 10^{-4} M Na_2MoO_4 (Fig. 16). In the presence of molybdate ions the zeta-potential of molybdenite becomes slightly more negative and the flotation recoveries decrease. Chander and Fuerstenau postulated that the increase in molybdate ions may also increase the adsorption of $HMoO_4^-$ or $MoO_4^{=}$ (depending on pH), and, as a result, the zeta-potential becomes more negative. The higher zeta-potential of molybdenite in the presence of molybdate ions probably increases the double-layer repulsion between the bubble and the particle, as a result of which the flotation recovery decreases. The relationship between the zeta-potential and the flotation recovery for this case is shown in Fig. 17. The depressant effect on MoS_2 flotation of molybdate ion is quite significant for molybdenite-producing operations because the concentration of Na_2MoO_4 (10^{-4} M) used by Chander and Fuerstenau[3,6] is equivalent to 9–10 ppm Mo in solution, which is well within the concentrations found, for example, in Climax recycle mill water.[33] In the absence of additional reported information on the effect of inorganic anions on molybdenite flotation we can assume that, because of the existence of numerous other inorganic anionic species in mill waters, other effects remain to be found.

Fig. 16 Zeta-potential and flotation recovery of leached molybdenite as a function of pH with and without molybdate ions present. After Chander and Fuerstenau[3,6]

Fig. 17 Flotation recoveries of molybdenite as a function of zeta-potential. After Chander and Fuerstenau[3,6]

The picture is further complicated by the fact that in mill waters the existence of F^-, $SO_4^{=}$, Cl^- and other inorganic anions in addition to inorganic cations and organic compounds (tannin, humic acids and flotation reagents) implies the existence of cationic, anionic and organometallic complexes. For example, fluoride ions are known to form the following complexes with Al^{+3}, Fe^{+3}, Mg^{+2} and Mn^{+4}: AlF^{+2}, AlF_2^+, AlF_3, AlF_4^-, AlF_5^{-2}, AlF_6^{-3}, FeF^{+2}, FeF_2^+, FeF_3, MnF^{+2} and MgF^+. Similar behaviour is found in the SO_4^{-2} and Cl^- complexes. Tannic acid is known to reduce Fe^{+3} to Fe^{+2} and form a very stable cationic complex. A systematic investigation of water chemistry effects on molybdenite flotation and other sulphide systems will require construction of the potential–pH diagrams of all chemical species in solution to define predominant chemical species in solution. Once this has been achieved, experimental testing of the effects caused by the species to the molybdenite surface has to be carried out to describe their ultimate effect on MoS_2 flotation.

Effect of organic species

Some of the commonly used reagents for depressing molybdenite are organic hydrophilic polymers such as dextrin, starch, glue, dyes and condensation products of aldehydic substances with aromatic sulphonic acids. In addition, tannic and humic acids, known to exist in

Fig. 18. Zeta-potential and flotation recovery of molybdenite as a function of pH in presence of Syntex. After Hoover and Malhotra[9]

recycle mill waters, have also been reported as molybdenite depressants. The two publications in this area have been those of Wie and Fuerstenau[29] on the effect of dextrin on the surface properties and floatability of molybdenite and by Hoover and Malhotra[9] on the effect of Syntex (sulphated coconut oil surfactant) on the flotation of MoS_2 from Climax ore. The effect of Syntex (Fig. 18) is to make the flotation and zeta-potential of molybdenite practically independent of pH. Hoover and Malhotra[9] explained this behaviour in terms of specific adsorption of Syntex on the edges of molybdenite, which, according to Chander and Fuerstenau[3,8] provide most of the negative charge of molybdenite.

Discussion

The information published to date has important practical implications for molybdenite processing operations. The experimental evidence on the effect of inorganic cations and colloids indicates that the only MoS_2 'surface-active' cation has been found to be Ca^{++}, although some preliminary experimental data show Mg^{++} and Ba^{++} as other 'surface-active' cations.[32] Ca^{++} adsorption has also been proved to be beneficial for molybdenite flotation by decreasing the zeta-potential down to the 'point of zeta reversal', higher concentrations being detrimental. All other inorganic cations studied and reported in the literature have no apparent effect on the recovery of molybdenite by flotation, with the exception of Fe^{++}, Fe^{+++} and Al^{+++}, which produce a large depressant effect on MoS_2 flotation in the pH range in which the hydroxides of these metals form.

Experimental evidence exists to show that molybdenite depression by salts of Fe^{+2}, Fe^{+3} and Al^{+3} is due to the coating of MoS_2 particles by hydrophilic hydroxides slime. As was mentioned previously, this fact is particularly clear for aluminium salts (Fig. 15), experiments having shown that they have the greatest depressant effect on molybdenite in the pH 4.5–8 range, which coincides with the pH range of precipitation of $Al(OH)_3$. The conditions that promote slime coating have been studied and reported by several investigators[16,18] and they can also be determined by use of DLVO[17,18] theory. Briefly, these conditions can be stated as follow.

(*a*) Slime coatings are promoted when the slime is charged opposite to the mineral that is being floated.[18-22] The larger the difference in magnitude of charge, the higher is the slime coating effect.

(*b*) Slime coatings are also promoted when the slime is uncharged or when the mineral being floated is uncharged.[21,22]

(*c*) The particle size of the slime has a pronounced effect on slime coating and, in general, the finer the slime particles, the greater is the depression of flotation.[22]

(*d*) Slime coating can also take place, but is less likely, when the slime and mineral that are being floated have equal charges, provided that the zeta-potential of the mineral, particle size of the slime and hydrodynamic conditions are favourable for this phenomenon to occur.[9]

(*e*) Higher concentrations of slime increase the 'slime coating' effect.[22]

As was pointed out previously, molybdenite shows a negative zeta-potential throughout the pH range with an apparent zpc at pH 2.3, whereas colloidal $Al(OH)_3$ particles were reported to have a zpc between 5 and 9.[24,25] Hence, very favourable conditions exist for heavy $Al(OH)_3$ slime coatings to take place on molybdenite at pH values below the zpc of $Al(OH)_3$, and this will eventually result in the depression of molybdenite flotation in this pH range. This can be clearly observed in Fig. 15. The stronger depression effect of aluminium salts on molybdenite when NaOH is used instead of $Ca(OH)_2$ as a pH modifier can be traced to the higher negative zeta-potential on molybdenite obtained when NaOH is used. As is shown in Fig. 5, the use of NaOH promotes a heavier 'slime coating' effect, resulting in increased depression of molybdenite.

Readers' attention should be drawn to the fact that the aforementioned explanation might be an oversimplification of the actual mechanism. It is now well established[23,26] that well below the concentration at which bulk hydroxides are formed, ions of aluminium and iron show complex behaviour. Polymeric ions, almost colloidal in size, can be formed that have high molecular weights and high positive charge and might also interact with the molybdenite surface. This area of research is a complex field that is still imperfectly understood, and much more fundamental work is required for a better understanding of this phenomenon.

Probably the most important practical effect is that of iron salts and colloids on the floatability of molybdenite, because they are continuously produced in the grinding stage when steel grinding media and steel-lined mills are used. Also, they represent one of the most abundant

Fig. 19. Relationship between zeta-potential of MoS_2 and pH in presence of 1×10^{-3} M iron salts (HCl and NaOH used for pH adjustments)

water components found in recycle mill waters. The experimental results reported by Lenkovskaya and Stepanov[11] in Fig. 14 show the very strong depressant effect of ferric salts on molybdenite flotation, particularly in the presence of lime. To explain this phenomenon the zeta-potential of molybdenite in the presence of Fe^{+3} and Fe^{+2} was measured in the absence of Ca^{++} (Fig. 19). The potentials obtained in the presence of Fe^{+2} show that the effect of this species on the surface properties of molybdenite is minimal (non-surface active), whereas Fe^{+3} has a significant effect on the mineral surface in acid medium. Ferric hydroxide would have precipitated at these pH values, and the positively charged colloidal $Fe(OH)_3$ would have adsorbed (slime-coated) on the negatively charged MoS_2 particles under these conditions. The zpc of $Fe(OH)_3$ has been reported at pH 6.7.[28] Consequently, the slime coating of $Fe(OH)_3$ on MoS_2 is broken at about pH 7. Nevertheless, the floatability of MoS_2 still remains high in the same pH range (see Fig. 14). A possible explanation is that, in the case of molybdenite, the zeta-potential is strongly influenced by the charged hydrophilic sites (edges) whereas flotation is determined primarily by the hydrophobic part of the surface (faces). The $Fe(OH)_3$ adsorption on MoS_2 in the acid pH range should take place mainly along the strongly negatively charged MoS_2 particle edges, which does not affect the hydrophobic faces and, therefore, the floatability of MoS_2. As far as iron salts are concerned, apparently the rate of formation and range of precipitation of $Fe(OH)_3$ depends to a substantial degree on the type of alkali reagent used and the degree of dispersion and particle size.

Lenkovskaya and Stepanov[11] reported that when $Ca(OH)_2$ is used as a pH modifier a finely dispersed, slowly precipitating iron hydroxide residue is observed, whereas in NaOH the precipitate becomes gel-like and rapidly coagulates. The precipitates produced in Na(OH) and $Ca(OH)_2$ were analysed by X-ray diffraction and found to be amorphous substances; but the latter contained a substantial amount of $CaCO_3$. Clearly, the iron hydroxide precipitate vigorously adsorbs Ca^{++} from

Fig. 20. Potential-pH diagram for Fe-H_2O at 25°C (solid line represents boundaries between solid-solid or solid-liquid phases, dashed lines represent boundaries between soluble species)

solution, which gives a basis to explain the differences in MoS_2 floatability noted in Fig. 14.

The stronger depressant effect of $Fe(OH)_3$ on molybdenite flotation when $Ca(OH)_2$ is used as pH modifier was observed in Fig. 14. These results can be explained in terms of the 'surface-active' character of Ca^{++} on molybdenite, which results in a decrease of the zeta-potential (Figs. 5, 6 and 7) and an enhancement of the 'slime coating' effect. In addition, the smaller particle size of the iron hydroxide precipitate obtained in the presence of lime, and the increased calcium adsorption on molybdenite in the presence of iron will also contribute to enhanced molybdenite depression. The experimental fact that at pH >12 the sorption of iron decreases, and in doing so the floatability of molybdenite is restored, can be explained by observation of the potential-pH diagram for iron shown in Fig. 20, where at pH >12 $Fe(OH)_3$ will be solubilized mainly as the ferrate ion (FeO_4^{--}).

The practical implications of the previous discussion and experimental findings for molybdenite-producing operations can be visualized by the fact that MoS_2 concentrate regrind plants at Climax[26] and Questa[32] use pebbles rather than steel balls. On the other hand, operations at Endako,[27] which started their regrind plant with pebble-mills, later switched completely to steel grinding media with no reported losses on recovery. Operations at the Endako regrind plant are reported to be carried out under conditions in which enough sodium silicate is added to adjust the pH between 9.8 and 11.0, which essentially means that the operations at the Endako regrind plant are consistent with the results presented in Fig. 14 by Lenkovskava and Stepanov[11] for the NaOH + $FeCl_3$ system, where the detrimental effect of iron is minimal in the pH range under consideration.

Experimental observations also have proved that the 'slime coating' effect on molybdenite flotation increases with increasing grade of the product that is being treated, which also explains the efforts in commercial practice to maximize the use of available fresh water in the regrind and cleaner flotation stages.

Therefore, the results reported in this review provide a practical solution for overcoming the detrimental effect of ferric hydroxide 'slime coatings' on molybdenite flotation. Also, the effect of anionic inorganic and organic species has been proved to be important—probably more than the 'slime coating' effect of inorganic colloids. Nevertheless, the state of our knowledge in this area is very limited and a systematic research effort will be required to find additional information on the effect of inorganic anionic and organic species on the floatability of molybdenite and other sulphide ores.

Conclusions

The 'state of the knowledge' of water chemistry effects on molybdenite flotation can be briefly stated.

(1) Colloidal slimes and inorganic anions have the largest detrimental effect on molybdenite flotation.

(2) At the concentrations that are usually found in mill recycle waters inorganic cations, except for Ca^{++}, and such organic materials as tannic and humic acids, with the exception of organic flotation reagents, have no apparent effect on the recovery of molybdenite by flotation.

(3) The only molybdenite 'surface-active' cation reported to date is the Ca^{++}.

(4) Low concentrations of Ca^{++} are beneficial for the flotation of molybdenite by reducing the zeta-potential up to the 'point of zeta reversal', but higher concentrations have been proved to be detrimental.

(5) Adsorption of Ca^{++} on the surface of molybdenite increases with an increase in the residual concentration of free $Ca(OH)_2$ and with an increase in the pH of the medium.

(6) When iron colloids are present adsorption of Ca^{++} on molybdenite increases, the increase seemingly being connected with the vigorous adsorption of Ca^{++} by precipitated iron hydroxide.

(7) A large depressant effect on molybdenite flotation is produced by inorganic salts of Fe^{+2}, Fe^{+3} and Al^{+3} in the pH range at which the hydroxides of these metals form.

(8) A lime medium intensifies the depressant effect of inorganic iron salts.

(9) Maximum adsorption of iron in a lime medium is observed in the pH range 10–12.

(10) Above pH 12 the depressant effect of iron disappears, and for aluminium it takes place above pH 10.

(11) The only reported inorganic anionic species that is detrimental to molybdenite flotation is the MoO_4^{--} ion. Additional work is required to identify other detrimental inorganic anionic species.

(12) Very limited fundamental research has been reported on the effect of organic ions on molybdenite flotation, and only one reference is available that is related to the effect of dextrine on the surface properties of MoS_2 in a flotation system.

Use of lignin sulphonate as moly depressant boosts recovery at Twin Buttes

T. O. Hiscox, Caribou concentrator superintendent, Bathurst, N. B.; and Dr. M. C. Kuhn, manager, process technology Natural Resources Group, The Anaconda Co.

T. B. Buza, technical service metallurgist, Water Treating and Mining Chemicals Div., American Cyanamid Co.

A NEW SYSTEM USING LIGNIN SULPHONATE to depress molybdenum has allowed increased production of salable by-product molybdenum concentrates at the Twin Buttes complex in Arizona. In searching for reagents to separate insolubles—including clays and talc minerals—from molybdenum concentrates at Twin Buttes, The Anaconda Co.'s Metallurgical Research Department discovered that large quantities of lignin sulphonate, in combination with a high-pH milk-of-lime, depressed the molybdenite while allowing talcs and clays to float.

The Twin Buttes property is a typical porphyry copper operation now owned by Anamax, an Anaconda-Amax joint venture. Open-pit mining recovers ore for treatment in a 30,000-tpd flotation concentrator. As is common at most copper operations producing molybdenum, molybdenite (MoS_2) is recovered by flotation along with the copper minerals in the concentrator, resulting in a copper-moly concentrate. Molybdenum values are then separated from the copper in a concentrate by-products plant.

The use of lignin sulphonate to depress moly originated as a response to problems experienced in the operation of the Twin Buttes moly plant. After extensive laboratory testing and further testing and refinement on a pilot plant scale (Fig. 1), this process is now a part of the installation.

The Twin Buttes moly plant consists of two circuits: a primary circuit, which separates molybdenite from the copper sulphides, and an insoluble circuit, which upgrades the moly concentrate.

Copper-moly concentrate is fed after thickening to the head of the primary circuit, where it is conditioned with sodium hydrosulphide (NaHS), then processed through a rougher and seven stages of countercurrent cleaner flotation. Here copper minerals are depressed, and moly is recovered as a primary concentrate. Tailings from this circuit are sent to the final copper spray dryer, while the molybdenite concentrate is either sent to final moly spray dryers or treated in the insol circuit for further upgrading.

The insol circuit as originally installed consisted of a thickener, a spray dryer, and two stages of flotation (Fig. 2). The pulp from the thickener was spray dried to remove the collectors from the sulphide mineral surfaces. The two flotation stages then floated the gangue and discarded it, while the moly tails were sent to the final dryers.

Although the original insol circuit produced good metallurgical results (Table 1), a problem developed in the capacity of the system to treat the volume of primary con-

centrate produced. Due to the variable nature of the Twin Buttes ore,, the gangue at times contains amounts of talc-type layered silicates and alumina clays, such as montmorillonite, in addition to the normal carbonates and silicates. The layered silicates and clays are naturally floating and report to the primary concentrate along with the molybdenite. When present, these gangues dilute the moly concentrate, increase the volume, and may cause the grade obtained to drop as low as 15% Mo.

The original design specifications at Twin Buttes provided for a 1,200-tpd feed of copper-moly concentrate containing 1% Mo. The primary circuit was expected to produce approximately 24 tpd of moly concentrate, and the insol circuit spray dryer was designed to handle the load. However, depending on ore type and concentrator performance, the feed to the primary circuit may contain up to 2% Mo at feed rates over 1,400 tpd. This increased production,, along with increased bulk due to dilution of the primary concentrate, may deliver over 75 tpd to the insol circuit. At this production level, the insol circuit was overloaded,, with the spray dryer being the bottleneck.

The problem, as presented to the Anaconda laboratories, was to develop a circuit that would produce final grade molybdenum concentrates from these higher tonnage, lower grade primary concentrates.

Lab work develops basic moly-insol circuit

Phase 1 of the laboratory test work centered on finding insol depressing mechanisms that could be employed in the primary circuit to depress the talc and clay minerals. The results were generally not good. Phase 2 centered on insol depressing schemes that would operate on the primary moly concentrate in the insol circuit. For a while these efforts also met with little success.

Fig. 3—Schematic of basic laboratory setup

During this second phase, it was discovered that lignin sulphonate, normally an *insolubles* depressant, tended to have the reverse effect when present in large quantities—it depressed molybdenite, which is naturally floatable. Lignin sulphonate, a common by-product of paper pulp mills, has been used on a limited basis in mineral processing as a binder material, dispersant, and emulsifier. The reagent is inexpensive (about 8¢ per lb) and is readily available under many trade names, such as "Orzan" and "Lignosite."

Further laboratory investigation produced very encouraging results using lignin sulphonate to depress the moly while allowing gangue to float. A basic circuit was developed (Fig. 3), in which the primary moly concentrate was conditioned at reduced percent solids with lignin sulphonate and milk-of-lime (CaO). The layered silicates and clays were then floated off in a three-stage countercurrent flotation circuit, which produced a throwaway second cleaner concentrate and a final moly concentrate from the rougher tails. Retention times used in the laboratory circuit were a 20-min conditioner stage, 20-min rougher flotation, 15-min first cleaner, and 10-min second cleaner.

Extensive batch flotation tests were conducted using daily samples from the moly plant's primary circuit. Feed ranging from 27.7% to 48.1% Mo was run through the open circuit, and recovery from the rougher tails was a consistently high 91% to 92.7%. Molybdenum grades obtained were good, ranging from 46.2% to 51.3% Mo (Table 2).

In addition, locked cycle tests were conducted to determine the effects of recirculating products. Locked cycle results show high overall recoveries of 96% to 99%, with moly grades of 47% to 48% obtained (Table 3). A comparison of locked cycle and open circuit results shows that the molybdenum concentrate is slightly lower grade in the locked cycle; however, a much higher recovery (approximately 4% to 8%) is obtained.

Data generated from the laboratory tests indicated that a pilot plant study was justified, and construction of the pilot circuit began in January 1973 at the Twin Buttes moly plant. Design of the pilot circuit was based on the expected feed rate from the high volume, low grade primary concentrates. The availability of salvage equipment from the previous Twin Buttes copper concentrator pilot plant made it advantageous to build the pilot circuit for the total expected feed from the primary circuit (1 to 3 tph), rather than split the flow of primary moly concentrate and use smaller equipment.

The pilot circuit, installed in place of the insol circuit, was started up in early March 1973. (See Fig. 1.) Underflow from the primary moly thickener was fed by ODS pumps to two surge tanks upstream from the conditioner. Feed to the circuit was bled off a recirculating feed loop from the surge tanks into the conditioner, which was constructed using cut-down Agitair No. 48 mechanisms in four compartments to minimize short-circuiting.

The conditioner overflow was fed by gravity to four banks of rougher cells consisting of a total of 20 Galigher No. 24 cells. The rougher tails were pumped directly to the final moly thickener, and the rougher concentrate was pumped to the first cleaner, consisting of eight Galigher No. 24 cells. First cleaner tails were pumped back to the conditioner, and the first cleaner concentrate was fed to the head of the second cleaner. The second cleaner, consisting of six No. 24 cells, produced a tail (pumped back to the first cleaner) and a throwaway concentrate.

Lignin sulphonate was metered to the conditioner by a Clarkson feeder, and milk-of-lime flow was controlled by a ball valve. Other reagents, if required, could have been added using a Clarkson feeder at any point in the circuit.

The pilot plant ran on a limited basis through the end of March, when it underwent circuit modification, including the installation of additional equipment and facilities. It was then restarted in June and ran through the end of July

Fig. 4—Molybdenum recovery and grade as a function of conditioner pH

1973. An average feed of 35.21% Mo was treated, producing a 45.87% Mo concentrate at an overall recovery volume of 91.11%. (See Tables 4 and 5.) Since the prime objective in the development of the process was the treatment of tonnages up to 3 tph, a five-shift, continuous production run was made at an average of 3.1 tph, with several shifts running over 4 tph. Metallurgical results compared favorably with the average results of the original spray dryer-insol circuit.

Key variables determined from pilot data

The relationship of key variables (retention time, lignin sulphonate dose, pH level, gangue mineralogy) in the circuit to the grade and recovery achieved was determined from the pilot plant data. In general, the retention time in the conditioner does not appear to be critical above a minimum time of 8 min. The lignin sulphonate dosage is determined primarily by the feed grade to the circuit—lower grade feed requires lesser quantities. At too low a dosage, the flotation of molybdenite is readily apparent in the roughers. At an excessive dosage, a number of problems occur, the most apparent being the formation of a persistent, voluminous foamy froth which defies control. The amount of lignin sulphonate normally used was in the range of 4 to 6 lb per ton.

Data indicate that a maximum recovery is achieved at a pH of 11.91, with higher pH values producing lower recoveries but higher grades (Fig. 4). Froth characteristics are also pH-dependent. A pH below 11.7 produces a persistent, foamy froth, while a value above 12.1 produces a brittle, watery froth that tends to carry slime molybdenite. The desired froth for good differential flotation is a tight, brown, heavy froth with the insol well flocculated.

The gangue mineralogy was determined by the difference between the *calculated* insoluble content and the insoluble content as determined by standard aqua regia digestion. This difference between the calculated and analytical assays is due to the presence of gangue minerals such as carbonates, sulphates, and chlorides, which will dissolve in the digestion and therefore not report as insol.

Fig. 5—Molybdenum recovery and grade as a function of gangue mineralogy

(See Fig. 5.) The circuit performs best on silicates and slags, and as the proportion of carbonates and sulphates increases, the recovery and grade both suffer. This is as expected, since the carbonates and sulphates are not naturally floatable. Their presence in the primary moly concentrate can normally be attributed to a physical entrapment in the froth during the primary flotation separation of moly and copper.

Laboratory work done on primary concentrate samples containing higher than average amounts of copper indicated that, with the moly depressed in the lignin sulphonate system, a xanthate collector could be added to activate the copper minerals and reduce the copper content of the final concentrate. While some activation of the moly occurred, preliminary results from laboratory and pilot tests were encouraging (Table 6). Use of the collector lowered the overall molybdenum recovery value; however, there were some offsetting increases in concentrate grade. The copper content in the moly concentrate is a major price penalty, and work is continuing to further test and develop this system.

Table 5—Pilot plant average conditions

Evaluating the success of the new system

The new process using lignin sulphonate at Twin Buttes has indeed met the requirements that initiated its development. The aqueous moly-insol flotation system will handle primary molybdenum concentrates ranging in feed grade from 20% to 40% Mo at capacities up to *four* times the original spray dryer circuit, while maintaining equivalent metallurgical results. With this circuit on line, it is now possible to utilize both spray dryers for treating final moly concentrates, thus greatly increasing the capacity of the by-products plant. The major disadvantage of the system is its inability to effectively separate carbonate gangue from the molybdenite. If a considerable volume of carbonates is carried over into the primary concentrate, a molybdenite-carbonate separation will become necessary. □

MOLYBDENUM FLOTATION

Molybdenum recovery by flotation is carried out at AMAX's Climax Molybdenum Mine, Climax, Colorado, and at their Henderson Mine/Mill nearby, as well as at Moly Corporation's Questa, New Mexico, mine-mill.

At Henderson, all mill water is recycled, and only minewater is discharged. At Climax, 90% of the mill tailings decant water is recycled to the mill with 10% discharge to the stream. This location is in a net precipitation area, and the site, despite measures to intercept surface drainage, still serves a sizable catchment area. This single component recovery operation uses only recycled water in its mill. Discharge of the remaining 10% is necessary for water balance purposes.

Originally, the mine and mill operator camp for the Climax operation was located at Climax itself. Sewage was discharged to tailings and this according to Climax laboratory studies conducted at the time, resulted in a deterioration in molybdenum recovery. This was overcome by adding activated carbon to the tailings stream.

Several years ago, when the mining camp was moved to Leadville, Colorado, and its sewage was no longer added to the tailings dam, it was found that recoveries returned to normal without the need to add activated carbon. This occurred several years ago, and the results of these tests, which were not published, have already been transferred to the company archives.

INPACT OF STEARIC ACIDS ON MOLYBDENITE FLOTATION

An excerpt from a 1963 internal report by R. Meyertons of Climax Molybdenum Company provides clear evidence of the impact of stearic acid on molybdenite recovery by flotation. Stearic acid is generated when Na-stearate (soap) is present in water at a low pH. Sewage water is likely to contain stearates.

LEAD-ZINC FLOTATION

Mill tailings decant water is successfully recycled to the mill for Pb-Zn flotation at St. Joe Minerals' Fletcher mine and mill in Missouri to the extent that the mill and tailings achieve zero discharge.

More information on water management from this operation can be requested from:

IMPACT OF STEARIC ACID ON MOLYBDENITE FLOTATION

INTRODUCTION

The use of fatty acids to recover a mixture of tungsten, molybdenum sulfide and molybdenum oxide from by-product tailing pulp has been discussed recently. The test data here reported was obtained in 1960 and 1961 as part of other investigations involving the effect of oleic, stearic and caproic acids on molybdenum sulfide flotation. This data should not preclude investigation of mixed mineral flotation, but the investigator must be certain to check the effect of reagent combinations on rougher recovery.

TEST PROCEDURES

Standard laboratory batch tests were conducted with 6000 g ore lots, crushed to 8 mesh dry, ground wet in the laboratory ball mill with reagents specified at 50% solids. Flotation time is 12 minutes at 40-42% solids.

TEST RESULTS

The summary table discloses the essence of the results; even traces of stearic acid is detrimental to molybdenite recovery. The use of larger quantities of oleic acid and caproic acid in various combinations was not successful. Recovery with these reagents is also below normal.

These particular tests did not answer the questions:

1. Can fatty acids be used to improve flocculation of finely divided MoS_2 in present tailing pulp?

2. Are other fatty acids, such as oleic and caproic, also harmful when present in PPM quantities in the water supply?

These last two questions should be answered in any molybdenum sulfide scavenging program.

The underground Fletcher mine shaft is designed to collect underground water in a sump. Oils and greases are collected underground using skimmers.

At a lead-zinc mine, waste oil and grease after an underground repair job was discarded to an ore stream. Apparently, this interferred immediately with mill performance indicating the importance of keeping petrochemicals out of ore and water that is used in flotation operations.

COPPER-LEAD-ZINC

Numerous copper-lead-zinc massive sulfide ore deposits are mined in various parts of the world ranging from the extremely arid northern Cape Province of South Africa where Black Mountain Mineral Development Co. mines and mills a massive sulfide ore at Aggeneys, to the spectrum of complex and massive sulfide mines stretching from New Brunswick across the Canadian Shield to Manitoba; deposits in British Columbia, Alaska, Australia, Spain, Sardinia, Sweden, Finland, and many more.

Water quality is important in the flotation of concentrates from this type of ore. Several operations have experienced selectivity problems, one of which was identified as being due to soluble copper ions in the process water which activated sphalerite (ZnS) when the process calls for its suppression. This caused startup problems at Noranda's Goldstream concentrator in British Columbia. Acid mine drainage at pH 3 was used as process water in the concentrator built for the VAJASA project on the Yukon border. Soluble copper present in this water was identified as a cause of interference in the metallurgical separation of concentrates from this ore according to:

MIKE SMITH
Wittek Development, Inc.
2640 South Sheridan Way
Mississauga, Ontario L5J 2M4
(416) 823-7381

Black Mountain, Aggeneys, South Africa

At Aggeneys, water is expensive and because of the climate, the operation can achieve zero discharge. Numerous water quality effects have been noted, and several of these have been reported in the literature by TWIDLE and ENGELBRECHT (1984) and GRAHAM and HEATHCOTE (1982). This 3,000 tpd mill recycles only 0.7 m^3/t ore out of a total

use of 1.8 m^3/t water used in the mill. An additional 0.4 m^3/t ore fresh water is used for backfill of tailings,

Water management at this operation is described in Appendix I. TWIDLE and ENGELBRECHT showed the negative effects on copper recovery of using increased amounts of recycled tailings water irrespective of whether the pulp was aerated prior to flotation.

Initially, during start-up of this mine-mill complex, some oil and grease got into the ore accidentally. This was thought to have contributed to the initially poor flotation results.

700-1,200 m^3/d fresh water is used in the backfill plant. It is believed that the 500 ppm (or so) organics in recycled water would possibly result in a weakened cement.

High pyrrhotite levels in the ore have sometimes been correlated with copper recovery reductions. This effect is counteracted by installing an aeration circuit.

Higher percentage of fresh water use also improves the lead concentrate recovery.

Backfill containing cement occasionally gets into the mill feed together with ore and has been found to reduce copper recoveries assumed due to water quality effects.

When reclaimed tailings water is treated by soda ash addition, calcium is precipitated, the calcium hardness being dropped from 1,600 ppm to 100 ppm, resulting in an improved recovery in the lead circuit. Silver recovery was improved from 82.4% to 83.8% when this soda ash treatment was applied.

Elevated levels of Cu and Pb and collector in recycled water were reduced by activated carbon adsorption in laboratory tests, but this did little to improve copper recoveries.

Cu-Pb-Zn Mine-Mill G, Ontario

The following observations were pieced together from rough notes and may contain misleading errors.

3,850 tpd ore is treated by flotation for recovery of copper, lead-silver, and zinc-silver concentrates. Tailings contain about 20% pyrite. Ammonia is used for pH adjustment in the plant because of ease of handling and because after freight-costs are included, it is found to be economical compared to lime at over C$240/t. Lime is used in the effluent treatment plant.

ARID ENVIRONMENT - ZERO DISCHARGE POSSIBLE AND NO STREAMS TO POLLUTE

TAILINGS POND IN BACKGROUND

COLLOIDAL SUSPENSION IN RECYCLE WATER

80% of the water used in the mill (including firefighting and potable water) is recycled tailings water. This mill has been steadily improving its water recycle rate since 1972, and its objective is to use recycled water for 85% of its needs.

Water used in the mill-concentrator is made up as follows:

	m^3/t	%
Fresh Lake Water	0.5	10.4
Water in Ore Feed	0.02	0.8
Potable Water (Lake)	0.01	0.4
Recycled Water	1.92	78.4
	2.45	100.0

- When recycled tailings water (saturated with $SO_4^{=}$) is used for reagent mixing, it was observed that when ammonia and cyanide reagents are mixed, severe scaling occurs in the reagent system. Reagent feed control was then difficult, so fresh water is now used for reagent makeup.

- SO_2 and ammonia are premixed to form $(NH_4)_2SO_3$, which is added to the rod mill to depress zinc in the bulk Cu-Pb-Ag flotation step.

- Even though the sulfide ore is milled at an alkaline pH normally considered a cause of thiosalt generation, thiosulfate levels are only 100 mg/l in the milled pulp solution water, which is lower than in other operations. This is ascribed to lower reactivity of the sulfides in this ore.

- The mine uses cemented backfill. Lab tests indicate that cured backfill fragments in mill feed would reduce copper recovery and selectivity. Attempts to correlate calcium levels in the rod mill discharge with Cu recovery and grade were inconclusive. Could cement contain other components that interfere with flotation.

- On occasion, when selectivity problems were noted, soluble copper concentrations in process solutions were found to have increased from 6 to 12 ppm.

- Aeration ahead of flotation has three effects:

  - Improved copper flotability.
  - Enhanced galena flotation.
  - Depressed Fe sulfides.

- If aeration is too long, zinc flotation is enhanced thereby reducing primary selectivity.

° Fresh water is used in pump glands and for the Cu-Pb separation step.

Separation of Cu-Pb is impaired when recycle water is used at any point after the Cu-Pb bulk recovery. Fresh water is also used in the Cu-Pb concentrate launders.

With fresh water, a lead concentrate of 65-70% can be achieved by depressing Cu with Cyanide. With recycle water, the lead concentrate grade can get to 50% Pb with difficulty only. The actual species in recycle water that causes this drop has not been firmly identified.

Cu-Pb-Zn Mill M, Ontario

Mill M treats two massive sulfide ore types with different characteristics. One contains 40% sulfide; the other contains 25-30% pyrite. The following observations were pieced together from rough notes and may contain misleading errors.

A Cu-Pb-Ag concentrate is floated first in standard semi-bulk flotation arrangement. This concentrate is next treated by depressing lead with guar and SO_2 and floating the copper. Zinc is floated from the primary flotation tails. SO_2 helps Cu to float.

Soda ash is used for the primary Cu-Pb concentrate flotation circuit which is operated at pH 9-9.5. Sometimes SO_2 is used in the rod mill when the ore is not "clean."

Recycle water use is found to cause lower concentrate grades in the Cu-Pb separation step. Fresh water use at this point gives the best results.

Recycled water is used without difficulty for flotation of zinc from the primary flotation tailings.

Some thiosulfate is generated because sulfide ores are milled at pH 8.5.

Fresh water is added in the ball mill circuit because recycle water results in higher zinc levels in the Cu-Pb semi-bulk flotation step.

When SO_2 is not added in the rod mill, the Cu-Pb grade drops immediately.

Excess collector added at the front end of the circuit ruins selectivity of the first semi-bulk float step. Consequently, this plant runs on starvation levels of collector.

Na_2CO_3 is used for pH adjustment in the mill. Some NH_3 has been noted in this circuit which is probably a residual from underground blasting. Soda ash promotes recovery of silver sulfides--tetrahedrite, freibergite, tennantite.

Activated carbon is added to recycle water to adsorb any extraneous collectors.

Composition of reclaimed water varies with the season, e.g.:

	Winter January, 1984	Summer July, 1984
pH	6.8	3-7
Zn ppm	5.9	3.1
Fe ppm	4.70	0.9
S_2O_3 ppm	43	Tr
Pb ppm	N/A	0.06
Cu ppm	0.01-0.04	0.01
Suspended Solids	25	1.0

Goldstream Concentrator, British Columbia

MCTAVISH (1984) described initial difficulties experienced at Noranda's Goldstream operation in British Columbia which recently shut down.

The copper-lead-zinc complex ore was milled and subjected to a standard Noranda-type flowsheet in which a copper-lead concentrate is first selectively floated from the tailings in which sphalerate is depressed. Subsequently, the sphalerite is recovered as a separate concentrate, and the Pb-Cu bulk concentrate is separated into two concentrates and cleaned. In this case, when the mill was started up, the metallurgy did not respond as predicted in pilot and laboratory tests. Grade and separation of the concentrates was poor.

Eventually, the problem was identified as being due to soluble copper in the process solution. This came about because the ore contained a small layer of soluble oxidized copper ore which contributed copper to the solutions. By selective mining, thereby avoiding getting this part of the ore into the mill, the problem was solved and and design selectivity, recovery, and grade were achieved.

Cu-Pb-Zn - USE OF HEXAVALENT CHROMIUM

Hexavalent chromium is metallurgically useful in flotation circuits because it is a powerful depressant. particularly for galena. As such, it is useful in making separations of minerals or in cleaning concentrates in which, say molybdenite, is depressed but non-mineral slimes floated.

In days gone by when mill tailings were discharged without knowledge of how effluents effect the environment, the use of dichromate was of less concern as effluents were simply discharged, and water lost in this way was replaced by fresh water. Since discharge has become an environmental concern and mills are obliged to strive toward zero discharge, mill tailings solutions have to be recycled.

If there is even a low level of hexavalent chromium in reclaimed water that is used in the front end of Cu-Pb-Zn flotation mills, the dichromate will cause a reduction in lead recovery because galena recovery in the primary Pb-Cu semi-bulk float would be reduced.

Some mill designers believe that hexavalent chromium will be reduced in mill tailings ponds that contain thiosulfates generated in the milling process. However, at one such operation, namely Newmont Mining Company's Idarado Mine near Telluride, Colorado, this did not occur sufficiently to remove all traces of hexavalent chromium which was detected in groundwater downgradient from the Idarado mill tailings.

Senior Newmont metallurgical staff point out that if Cr^{VI} is to be used in a flotation step, then water used in this circuit must be kept totally isolated from the rest of the mill and the tailings to be sure that not even a trace gets into the main mill solution. Comments by Lynn Harris of Newmont Mining Corp. and by Per Broman of Boliden Metall AB, Sweden, are interesting observations.

EXXON Minerals Company, Crandon Project

EXXON Minerals Corp.'s Crandon mine and mill, now in late stages of investigation in Wisconsin, proposes to recover copper, lead, and zinc from a complex sulfide orebody.

The flowsheet proposed for this project has not yet been released, nor has the environmental impact statement, which will describe in detail the process, water recycling, water management, and effluent treatment and discharge measures to be applied.

When this environment impact statement is published, this ought to be a very valuable state of the art document because Exxon is known to have gone to great lengths to study all aspects of water recycling and treatment for reuse or discharge. Because of climatic constraints, this project will not be able to achieve zero discharge.

Individuals and consultants known to be involved in various aspects of this study for Exxon Minerals Corp. include:

Golden, Colorado 80401

Dear Hans:

Many thanks for your letter of April 20, 1984 and the copy of Randol's report "CIX-RIP For Uranium Recovery".

With respect to hexavalent chromium in flotation, I note the following: You are probably right that thiosulfate ions are formed during the grinding of sulfide ores in an alkaline pulp. The problem is that sodium dicromate is not added to this circuit. It is added to the copper/lead separation circuit where little or no thiosulfate is present. Based on our experience, I think that it is dangerous to rely on the reduction of hexavalent chromium to trivalent chromium by means of thiosulfate in the tailings dam. It most certainly did not happen in our case.

When I checked into this matter about a year ago, I talked with Norman Holme, Chief Metallurgist, Cyanamid who noted that in the Missouri lead belt where dichromate is used for copper/lead separation, the water is always kept separate except at the Magmont mill where only 25 percent water is recycled. Deleterious results were experienced in the early days of operations in the Missouri lead belt.

Dichromate is a potent depressant even in very small quantities so that apart from the toxicity problem, one can expect problems in the flotation plant. In our opinion, the copper/lead separation circuit should be clearly isolated from the rest of the circuit to prevent these problems.

Best personal regards.

Sincerely

Leonard Harris

LH:emd

Dear Mr von Michaelis,

Thank you for your note on Cr (VI) reduction by thiosulphate ions. This has not been studied or even observed by us. We know however that thiosulphate could reduce Cu (II) to the monovalent or even elemental state. This is in fact what we think happens in the SO_2-promoted flotation processes.

Your idea actually made us consider this phenomenon being behind some so far unexplained Cr (VI) to $S_2O_3^{2-}$ ratios being observed in our effluent streams.

Thank you once more. We look forward to seeing your final report.

Yours sincerely,

Swedish Cu-Pb-Zn Concentrators

Two interesting papers are inserted below which describe how water is recycled in European base metal operations and provide an insight into some of the testwork that is being carried out on water reuse in complex sulfide ore circuits.

Water reuse at sulphide ore concentrators in Sweden: practice, experience and current developments

Per G. Broman Dr. Eng.
Sala International AB, Sala, Sweden

Synopsis

The scarcity of fresh water resources that are available to the mining industry and the desire to reduce effluent discharge from mining and processing operations are the main reasons for the reuse of process water. The processing of complex sulphide ores by flotation is characterized by very strict demands on the chemical composition of the water phase. Usually, therefore, the introduction of reclaimed water is considerably more complicated than is the use of fresh water. First, certain reagents have been added to this water, some of which remain, and, secondly, complex ores are greatly affected by wet oxidation during the flotation process, which results in considerable release of various ions and salts in the water phase.

The fresh water source, along with the entire operational area (mine, concentrator and tailings pond) and the receiving point, should be regarded as one integrated system of water management. It is important to consider water reuse not only from the point of view of water flow but also from that of pollution. In principle, it would be possible to reduce the flow of water by reuse without actually reducing the flow of contaminants.

Reuse is accomplished by internal-circulation loops within the plants as well as by circulation from the tailings and clarification ponds (referred to here as external circulation). Practice and experience of water reuse in Swedish sulphide ore concentrators are illustrated with examples from ores of varying complexity. The examples have been selected to include cases in which reuse has increased above tolerable limits: in general, reuse-water additions to the final grinding and flotation circuits have detrimental effects on the metallurgy. The metallurgical implications of water reuse and the associated mechanisms are under investigation by mining companies and the Swedish Mineral Processing Research Foundation, and such a study is described.

The treatment of complex sulphide ores by flotation to produce clean concentrates with the highest recovery possible demands very stringent and closely controlled processing—this applies particularly to the composition and properties of the water phase.

In Sweden, with its comparative abundance of water, the *quality* of the fresh water supply seldom poses any problem; to reduce the *consumption* of fresh water the reuse of process water would be appropriate. Another, and usually more important, reason for reuse, however, is the desire to reduce effluent discharge from the mining and processing operations. The use of reclaimed water is normally much more complicated than that of fresh water: first, certain reagents have been added to the water, some of which remain in it, and, secondly, complex ores are characterized by a strong tendency to increased weathering during the wet oxidizing conditions of the flotation process, which results in the considerable release of various ions and salts in the water phase.

To determine the effects of the reuse of process water in various ways and in various types of plants on the flotation process comprehensive studies are carried out by research establishments and mining companies, and present practice in terms of water reuse and current research is summarized here.

Principles and aims of water reuse

Before details are given of the reuse of water in actual practice it may be of interest to summarize reuse in relation to the overall aim. Fig. 1 shows a broad water flowsheet. Ore treatment requires, depending on the specific process, a flow of water that is directly correlated with the flow of ore. Clearly, the reuse of water in an internal or an external loop will influence the demand for fresh water: one of the main purposes of the reuse of process water is, therefore, that of reducing the demand on the fresh water supply. Reuse might also offer the possibility of increasing ore throughput in existing plants without any increase in the consumption of fresh water above the limits that have been set by prevailing regulations.

Fig. 1 General water flowsheet

Fig. 1 shows that there is a somewhat more complicated balance for the tailings pond. Effluent flow from the tailings pond to the recipient depends on the inflow of tailings suspension, direct atmospheric precipitation and surface drainage and the outflow by evaporation and recirculation. Furthermore, some of the inflowing water is retained as residual water in the dam and some water is lost throug'. infiltration into adjoining soil layers.

Internal and external reuse affect the water balance of the tailings pond in different ways: inflow to the tailings pond will be influenced by the internal recirculation only, but both will reduce effluent flow to the recipient. This is the second main purpose of reuse.

So far only the balance of the water flows has been discussed. Clean water as such seldom imposes any serious burden on the recipient. More important is consideration of the flow of pollutant material.

The principal additions of pollutants to the water take place during the concentration process. Recirculation demands the use of a process water that usually contains somewhat higher amounts of dissolved components than the fresh water. Depending on the chemical and physical conditions that prevail during the process there will be a build-up of added substances and reaction products in the water. The concentration of the added substances is usually far below the saturation level. As regards ions, which are formed by weathering of the ore, the supply of solid reactant is generally very large. Despite ample additions of oxidizing reactant by aeration a marked shortage prevails throughout the flotation process, a considerable contact period with the atmosphere being necessary before the oxygen deficiency is removed. Thus, the limited residence time will prevent saturation concentration from being reached. Recirculation of water in such a system will increase the contact time and, in principle, make it possible to attain a higher concentration of oxidation products in the water.

The inflow of surface drainage to the tailings pond will usually have a diluting effect on the water in the dam, ignoring here the extreme cases of acid precipitation and inflow of water from acid or other polluted ground.

In summary, the concentration of cumulative substances in the tailings dam water can be affected by reuse and also by dilution through precipitation. Hence, water reuse will yield a lower effluent flow to the recipient but may, in principle, give an unchanged discharge of substances that may accumulate in the water. Similarly, precipitation and surface drainage will yield a larger volumetric flow, but not necessarily a greater discharge of pollutants.

The above discussion relates to the flow of cumulative substances from the viewpoint of the *recipient* only. The question of the concentration that can be accepted from the viewpoint of the *process* is completely separate and may well be the limiting factor as to the extent to which reuse is feasible. It should be noted that dilution from atmospheric precipitation is normally beneficial to reuse, but if dilution and, hence, water quality vary considerably, the maintenance of consistent process conditions may be jeopardized over a period of time.

Fig. 2 General water flowsheet, including mine water

To further illustrate this complex subject a general flowsheet that includes mine water is shown in Fig. 2. In the total water balance of the mine and concentrator it is natural to include the mine, which may constitute an important water source. Mine water may go to the concentrator as a substitute for external water supply, to the tailings pond for cleaning or to separate cleaning before discharge to the recipient.

Mention was made above to the fact that reuse can be accomplished in internal and external loops.

An *internal reuse loop* comprises recirculation of water from dewatering units inside or directly connected to the concentrator, which normally necessitates dewatering of concentrate or tailings products by thickeners or filters. Dewatering of the middling products, e.g. zinc tailings prior to pyrite flotation, may also provide water for recirculation. A system of water exchange between the separate steps in a complex sulphide ore

concentration process is appealing from the process water chemistry viewpoint, but it has not been used to any great extent because of the fairly elaborate dewatering equipment necessary to obtain a water that is sufficiently clean with respect to solids.

An *external reuse loop* comprises water that is recovered from tailings and clarification ponds.

There is no basic difference between the uses to which water from the internal and the external water system is put, usage being determined by its composition.

Definitions of reuse and reuse percentage

Various definitions of the concepts of reuse and reuse percentage have been suggested. Here reuse implies deliberate action to reduce the demands on fresh water. A system at 'zero level' (no reuse) is a system with normal product flows, including recirculation of middling products within and between the flotation circuits, where any necessary dilution, in addition to the circulation of products, is made with fresh water.

Reuse indicates that the water has been used previously in the same process and that it is used in the process instead of fresh water. It was stated above that the water balance of the tailings dam in particular is very complex, the process water being diluted by precipitation and surface water. The dilution water is, in this respect, considered as part of the reuse water. Complicated boundary problems may arise in relation to circulation within grinding and flotation circuits. Diluted middlings products often contribute very significantly to dilution in the grinding and rougher flotation circuits, the need for external water for these operations thereby being reduced. Since the purpose is to return particles for regrinding, however, and water recirculation is merely a side effect, it is not considered as reuse.

Reuse percentage is defined as the percentage of the total need of process water (i.e. the demand for fresh water supply in the zero level system) that is covered by reuse.

Reuse practice and experience at Swedish sulphide ore concentrators

Current reuse practice at Swedish sulphide ore concentrators is briefly illustrated, the examples selected including cases in which reuse has been increased above tolerable limits to show the sensitivity of the process. The localities of the concentrators are shown in Fig. 3.

Fig. 3 Location map of Swedish concentrators

Kristineberg concentrator, Boliden Mineral AB

The Kristineberg concentrator is the central treatment unit for all the ores from the Kristineberg area, some 1 000 000 tons being treated per year. Five different ore types are treated in different campaigns. There are two parallel grinding and flotation sections: the simplified flowsheet (Fig. 4) is based on the *A* section; the broadly similar *B* section is normally used for ores with a low arsenic content suitable for pyrite extraction. Ores treated vary in composition and mineralogy from low-grade impregnations to massive pyrite ores, but they are as a rule highly complex. The ore that is fed to the concentrator grades 0.96% Cu, 0.52% Pb and 4.35% Zn, and the tonnage and grades of the Cu, Pb and Zn concentrates are given in Table 1.

Table 1 Kristineberg concentrate data (yearly average for all ore types)

Product	*Cu, %*	*Pb, %*	*Zn, %*	*Annual tonnage*
Cu concentrate	22.3	7.5	5.1	34 600
Pb concentrate	1.0	32.0	8.0	5 200
Zn concentrate	0.4	0.9	54.6	30 900

Concentrates are thickened, filtered and dried. The tailing, currently about 790 000 ton per year, is used in part for mine backfill. After desliming, about 60% of the tailings can be used for fill, the balance passing to the tailings pond. Fig. 5 shows a schematic water balance relating to an ore capacity of 900 000 ton per year. Reuse is performed in an internal and an external loop. The total process water demand of the concentrator is 715 m^3/h, of which 376 m^3/h, or about 53%, is covered by reuse.

Internally, water is recovered as thickener overflow and as filtrate water from the filtering of tailings sand. The water is used as dilution water for the final tailings before cyclone separation of sand for backfilling. Water from the external reuse loop is used in the rod-mills (together with mine water and fresh water), in the wet

Fig. 4 Kristineberg concentrator simplified flowsheet

Fig. 5 Kristineberg concentrator water balance (m^3/h)

scrubbers of the concentrate dryers, as dilution water for the backfill cycloning, as dilution and spray water in the pyrite flotation and as cleansing water. Water in the external reuse loop has the average analysis (monthly average for 1978) as shown in Table 2.

froth launders in all the flotation circuits. The amount of pond water was then 15–20%. Initially, no significant changes in the process result were noted, and after a little more than half a year of the use of pond water fresh water only was used for one week. The results obtained are shown in Table 3 and compared with those of the period immediately following when reuse water was again employed.

A clearly reduced selectivity against zinc was noted in the flotation of copper when tailings pond water was used. The zinc content in the copper concentrate increased by more than 6% at the same time as the copper grade in the copper tailing increased. Whether this was due to the reduced floatability of chalcopyrite or to activation of the sphalerite is not known. Reuse in this way obviously had a very negative influence and, accordingly, limited recirculation was resumed.

Table 2 Kristineberg water quality data—tailings pond water (values in ppm)

Unfiltered sample									
pH	*Turbidity, FTU*	*Conductivity, mS/m*	*Cu*	*Fe*	*Zn*	*Pb*	*As*	*Hg, ppb*	*Cd*
8.0	7.5	171	0.030	0.23	0.32	0.013	0.011	0.66	0.008
Filtered sample									
			Cu	*Fe*	*Zn*	*Pb*	*As*	*Hg, ppb*	*Cd*	*SO_4*
			0.012	0.059	0.211	0.005	0.008	0.21	0.008	589

It has been demonstrated that it is possible to use the water in a mixture with mine water and fresh water without process disturbance in relation to primary grinding and pyrite flotation. Full-scale tests have been performed over a period of several months on the use of the water for secondary grinding and as spray water in

Stekenjokk, Boliden Mineral AB

Stekenjokk mill is the most recent Boliden plant, the concentrator processing 600 000 t per year. The ore is a complex sulphide grading 1.4% Cu, 3.6% Zn, 0.31% Pb, 19% S and 40 g/ton Ag. The main sulphides are chalcopyrite, sphalerite and pyrite.

Table 3 Kristineberg metallurgical data on Näsliden ore with and without reuse

The ore is screened at 200 mm into fine- and coarse-ore bins and fed to the two-stage autogenous grinding circuit according to the flowsheet shown in Fig. 6. Flotation is performed stage-wise for copper and zinc. Part of the copper flotation is integrated into the grinding circuit as a unit flotation. The copper and zinc circuits are of conventional design; to the zinc circuit is added a Zn-upgrading circuit with the use of reverse flotation.

Fig. 6 Stekenjokk concentrator simplified flowsheet

The metallurgical results show a copper concentrate grading 19% Cu with 87% recovery and a zinc concentrate grading 53% Zn with 70% recovery. The concentrates are thickened, filtered and dried. The tailings are used partly for mine backfill after cyclone separation of the fines, which are pumped to the tailings pond. Of a total tailings tonnage of 538 000 per year, 78 000 ton are used for backfilling.

Fig. 7 shows a schematic water balance for the maximum permitted fresh water usage of 6 m^3/min. The total process water requirement is 8.1 m^3/min, of which 2.1 m^3 or 26% is covered by reuse. Internally, overflow water from thickeners is reused as dilution water for transport of backfill to the mine. About one-fifth of the external reuse is used as dilution water in the grinding circuit, the rest being used as water for cleansing. Unfiltered samples of the tailings pond water had the average composition during 1978 as shown in Table 4.

Fig. 7 Stekenjokk concentrator water balance (m^3/h)

For distribution of reuse water to any desired point in the concentrator there is a pipe system, which is parallel to the fresh water system. By use of this pipe system a test with increased reuse was run that comprised the addition of reuse water as dilution and spray water to the zinc flotation. The arrangement was maintained for several months, but then had to be discontinued because of severe losses of zinc. Although reuse of water was not the only reason for the deterioration, it was considered to be a significant factor. No close follow-up of the water composition during the period of extended reuse was made. A slight increase in SO_4^- grade around a base level of 100 ppm was the only significant change to be observed.

The lead concentrate grades 75.4% Pb and 1.1% Zn and the zinc concentrate grades 55.2% Zn and 1.7% Pb. The annual productions are 61 600 ton of lead concentrate and 12 300 ton of zinc concentrate. The flowsheet is shown in Fig. 8. The concentrates are thickened, filtered and dried. Tailings are cycloned for generation of a backfill material for the mine. The fine product is pumped to the tailings disposal area after the addition of lime to pH 11.2. Of the total of 1 300 000 ton of tailings, approximately 66 000 ton are used as backfill. The fraction pumped to the tailings pond is cycloned at the pond to generate a coarse product for dam construction.

According to the water balance shown in Fig. 9, fresh

Fig. 8 Laisvall concentrator simplified flowsheet

Laisvall, Boliden Mineral AB

The concentrator at Laisvall treats a lead–zinc ore grading 3.4% Pb, 0.6% Zn and 8–10 g/t Ag. The annual output of the mine is 1 400 000–1 500 000 t. Galena and sphalerite occur as the matrix in a hard white sandstone. The content of iron sulphides is very low. The ore is ground in rod- plus pebble-mills to 36% −44 μm and floated in consecutive stages for lead and zinc, respectively.

Fig. 9 Laisvall concentrator water balance (m^3/h)

water is supplied from Lake Laisan and from the mine. Internal reuse of water has been practised for several years. Reuse of water from the tailings pond was tried from February, 1979, to March, 1980 (see below).

Test period 1: mine water + tailings pond water
During the initial phase (test period 1) only mine (3 m^3/min) and tailings pond waters (4 m^3/min) were used, apart from the internal reuse of 1 m^3/min that was maintained throughout the series of tests. After a few weeks it was necessary to abandon the test because of severe problems due to precipitation in pipes and spray nozzles. The tailings pond water content of calcium (120 mg/l) and the mine water content of carbonate (60 mg/l) led to precipitation of calcium carbonate. Increased frothing indicated a build-up of frother in the system.

1.5–2 m^3/min. Mine water was fed at a rate of 4 m^3/min and the balance at up to 7 m^3/min, i.e. 1–1.5 m^3/min was supplied from Lake Laisan. Initially, the process did recover metallurgically (Fig. 10), but the target grade of the lead concentrate could not be fully attained.

Since the pH value of the process water mixture was lower than during test period 1 calcium carbonate precipitation did not occur. Fig. 10 shows that the late part of the period is characterized by a steady deterioration in lead concentrate grade. The test period was interrupted by ice blocking the return pipe from the tailings pond during a period of extreme cold.

Test period 4: mine water + tailings pond water
During the later part of February, 1980, the fourth test period was started, 4 m^3/min of tailings pond water

Fig. 10 Laisvall concentrator: Pb grade in Pb concentrate with and without reuse

Metallurgically, the tendency towards lower grade and recovery in the lead flotation was clear. According to Fig. 10, test period 1 yielded a deterioration in the monthly lead concentrate grade mean values.

Test period 2: lake water + tailings pond water
To allow for the continued use of tailings pond water the carbonaceous mine water was eliminated. The process water fed to the concentrator was a blend of fresh water from Lake Laisan (2 m^3/min) and tailings pond water (5 m^3/min). Slowly, but gradually, both the grades and the recoveries in the lead flotation were reduced. This was accompanied by increasing frothing problems, which resulted in frequent overflows of pump sumps. After about six weeks the grade of the lead concentrate had dropped by more than five units at an alarming increase in the tailings grade. The test period was then discontinued.

Test period 3: lake water + mine water + tailings pond water
To stabilize the process after period 2 the amount of tailings pond water was reduced from 5 to

being used. Fig. 10 shows that the lead concentrate grade was clearly affected, the impact being so marked that the mean value for February dropped by more than 1% in comparison with the January value, though the water arrangement was used for only ten days in February.

Test period 5: lake water + mine water + tailings pond water
In early March, 1980, it was decided to take steps towards the stabilization of the process. The tailings pond water addition was reduced from 3 to 1.5 m^3/min, the 1.5 m^3/min eliminated being replaced by water from Lake Laisan. As Fig. 10 shows, a further deterioration in lead grade was halted by the action to reduce tailings pond water. Whether this is a permanent stabilization or merely a temporary effect will be proved over a longer period.

Taking account of some additional observations, the following conclusions may be drawn: reuse of tailings pond water has a pronounced negative effect on the recovery and concentration of galena; the deterioration in lead flotation increases with time and possibly also

with the proportion of tailings pond water that is being reused; the process is quickly restored to its natural state after the shutdown of the reuse system; a mixture of mine water and tailings pond water could be used only if the pH of the mixture is low enough to prevent precipitates of calcium carbonate being formed that disturb the process; accumulation of frothing agents takes place in the reuse loop, which causes setbacks in the process by overfrothing; it has been possible (and necessary) to reduce the addition of frother by 25–50%, depending on the percentage of water that is being reclaimed, though without fully solving the frothing problem; and accumulation in the tailings pond water of the components calcium (from 70 to 125 mg/l) and sulphate (from 100 to 275 mg/l) has been observed.

Zinkgruvan, Vieille Montagne

Zinkgruvan, Sweden's largest zinc mine, has been owned since 1857 by the Belgian company Société des Mines et Fonderies de Zinc de la Vieille Montagne, S.A. Since 1977 the company has operated a new concentrator that treats 600 000 ton per year of an ore grading 8% Zn, 1.5% Pb and 35 g/t Ag. The main ore minerals are sphalerite and galena. Only minor amounts of pyrrhotite occur, and practically no pyrite. The gangue minerals are mainly quartz and feldspar, but up to 15% limestone and dolomite occur, making the host rock basic.

Fig. 11 Zinkgruvan concentrator flowsheet

Processing follows the flowsheet shown in Fig. 11; grinding is by primary autogenous grinding in one stage. The final grinding product has a particle size of 80% −140 μm. Galena and sphalerite are bulk-floated at pH 7–7.5. Generally, no special activation of the sphalerite is needed. Spontaneous activation is achieved by lead ions, dissolved from galena particles. After cleaning the bulk concentrate is reground in a pebble-mill and separated into a lead and a zinc concentrate by depressing the zinc. Zinc sulphate and sodium hydrosulphite are used as depressants and sodium hydroxide as pH regulator in the separation circuit. The concentrates are dewatered in thickeners, filters and driers. The final tailing is cycloned to generate a sand fraction for mine backfilling (approximately 175 000 t per year). The fines (approximately 333 000 t per year), together with the water, are pumped to the tailings pond. The tailings and clarification ponds give the water a nominal retention time of approximately three months. The lead concentrate grades 62% Pb and 12% Zn and the zinc concentrate grades 53.5% Zn and 0.6% Pb. Recoveries to the main concentrates are 87% for the Pb and 95% for the Zn.

Process control is mainly manual, an on-stream analyser being used as the basis for this control.

Fig. 12 shows the water balance. Overflows from the concentrate thickeners are combined and clarified in a middlings thickener, which is also used for thickening Pb cleaning rejects. Overflow from this middlings thickener is reused internally as dilution water for the backfilling system. Tailings pond water (after clarification in a clarification pond) is used for the same purpose and, to a minor extent, as spray water in the bulk flotation.

One reason for the bulk-selective type of flowsheet for the flotation relates to the aspects of water management. It was foreseen that the bulk flotation stage should be tolerant in regard to water quality and that the large-scale reuse of water should be possible. As soon as the

Fig. 12 Zinkgruvan concentrator water balance (m^3/h)

Fig. 13 Zinkgruvan concentrator: Pb and Zn grades in final Pb concentrate with and without reuse of tailings pond water

tailings and clarification ponds had stabilized after plant start-up, reuse of water was introduced on a large scale in July, 1978. The demand for process water to the grinding and bulk flotation sections was totally covered by water from the clarification pond at this stage.

Fig. 13 illustrates the development of the metallurgy during the period of reuse. The Pb grade in the final lead concentrate dropped from +70 to well below 60, a low value being recorded for week 47 (<55% Pb). The function showing the Zn grade in the lead concentrate is, not surprisingly, a mirror function of the Pb grade. The Zn grade increased from 5–7 to +17% by week 47. Since a 55% Pb and 17% Zn concentrate represents a very low commercial value it was necessary to take steps to improve the results. By cutting out the reuse loop and replacing tailings pond water by lake water, the deteriorating trend was broken. In a few weeks the concentrate grade had returned to the +60 side.

During the period of reuse the zinc concentrate remained fairly stable in composition, though the

Fig. 14 Zinkgruvan concentrator: Pb grade in Pb concentrate versus time with and without reuse

amount was influenced by the zinc losses to the lead concentrate. Along with the very clear deterioration in lead flotation week by week, as shown in Fig. 13, short time disturbances in hourly and shift by shift frequencies occurred that were difficult to master.

A typical example of such short-range fluctuations in the lead flotation is given in Fig. 14. Within a 16-h period four complete cycles of ups and downs are recorded for the reuse system, whereas the no-reuse system shows only two such periods. During the reuse period the addition of flotation chemicals had to be adjusted to compensate for the successively changing chemical conditions brought about by the reuse water. The most significant change in flotation characteristics was observed in the bulk flotation, in which the sphalerite became very difficult to recover. It was frequently observed that zinc losses suddenly increased dramatically—for example, from 0.15 to 1% Zn in less than one hour. Obviously, the spontaneous activation of sphalerite by lead ions was offset by the new system. By the addition of copper sulphate it was possible to reduce the zinc losses: this, however, had a strong impact on the separation circuit. The relatively weak mode of zinc depression used was clearly inefficient, despite the increase in the amounts of depressants. A fluctuating pattern for the lead concentrate grade (Fig. 14) is typical of this period.

The reuse water gradually lost its basic character during the test period. The addition of sulphuric acid to the bulk flotation circuit could be drastically reduced. Some typical data on water quality variation during the reuse period are presented in Table 5. The clarification pond overflow, which was reused, showed, periodically, significant contents of hydrogen sulphide. The reason for this obviously strongly reducing condition in the water system is probably complex: circulation of water could be one explanation; another might be the fact that the tailings and clarification ponds were newly taken into use for this purpose and that the content of organic matter in the ponds caused strongly anaerobic conditions.

At present the concentrator is reusing clarification pond water only for the backfilling system. A future new test campaign with more extensive reuse is under consideration and it is expected that the ponds will stabilize sufficiently for reducing conditions such as those experienced during the prior test period not to occur.

Reuse at Falu concentrator—a MinFo project

From the above it is evident that extensive activity is under way at many Swedish mines with the aim of reducing fresh water consumption and effluent flow. The activities are, as a rule, fairly specific, being governed by local conditions. Since many of the problems involved in water reuse are common to several plants, a study of the subject within the central R & D foundation, MinFo—Swedish Mineral Processing Research Foundation—was initiated. Since 1978 this study has had the objective of determining the metallurgical implications of reuse of a tailings pond

Table 5 Zinkgruvan water quality data during reuse period

Fig. 15 Falu concentrator simplified flowsheet

water at a complex sulphide ore concentrator. The plant selected is that of Stora Kopparbergs Bergslags AB at Falun (see Fig. 3).

The concentrator treats a highly complex and mostly compact pyrite ore grading 0.3% Cu, 2.0% Pb and 6.1% Zn at a yearly rate of 200 000 ton. After grinding in rod- and ball-mills to 80% −70–80 μm—a Cu–Pb bulk concentrate is floated and separated by depression of Pb (see Fig. 15). The Cu–Pb tail is floated for zinc and then for pyrite. After desliming in hydrocyclones 50% of the tailings (120 000 t per year) is used for backfilling. The fines are pumped to a tailings dam after the addition of lime to maintain a pH in the tailings pond effluent of at least 7. Tailings pond water had not previously been reused: reuse of such water could, in principle, be made in one or more of the four separate flotation circuits. To determine to which circuit to recycle tailings pond water and what reuse/fresh water ratio to use an indicative bench-scale series of tests was run.

It was realized that the metallurgical impact due to reuse could not be forecast from simple batch experiments. It was also felt that complicated cycle tests at the bench scale, though giving more substantial data, still leave too many time- and scale-related questions unanswered. It was therefore decided to use batch tests as very rough indications only and to assess the impact on the metallurgy at the full scale. Tailings pond water

Fig. 16 Falu concentrator water balance for 75% tailings pond water in mixed water system (m^3/h)

was used in different proportions than process water in Cu–Pb flotation, Zn flotation and pyrite flotation performed as single bench test runs. Based on the test results it was decided that tailings pond water should be reused for dilution and spraying throughout the process; fresh water alone should still be used for preparation of reagent solutions, vacuum pumps, sealing water and cleansing applications; and, where used, the reused water should be added in a 25% mixture with fresh water and, if no deterioration were observed, it should be increased to 75% proportion. The water system used is illustrated in Fig. 16. The tests were started in November, 1979.

A couple of weeks after start-up it was decided to increase the reuse percentage in the mixed water system from 25 to 75%. This high proportion, however, could not be maintained for more than two months because of severe pipe-blocking problems caused by precipitation of gypsum. The tailings pond water constituted a saturated calcium sulphate solution, which was brought to precipitation at the temperature increase when piped into the concentrator building. At present (March, 1980) the proportion of reuse water is 25% in the mixed water system.

Table 6 Falu concentrator reuse water quality, December, 1979

Temperature	2.5	°C
pH	7.0	
$S_2O_3^{2-}$	72	ppm
SO_3^{2-}	5	ppm
S^{2-}	0.5	ppm
SO_4^{2-}	1580	ppm

Zn	0.52	ppm
Oxygen	6.5	ppm
Conductivity	225.3	mS/m
Suspended solids	20.8	ppm
Suspended organics	2.0	ppm
Turbidity	14	NTU
Frothing	1.2	cm*

*Froth column developed during standardized aeration.

As a routine, the composition of the reuse water is checked at regular intervals—more frequently when changes are introduced. So far, no accumulation trends have been observed. The variations recorded are mainly functions of pH variations in the pond due to variations in the additions of lime to the tailings. A representative set of water quality data from the period with high reuse percentage is shown in Table 6.

The metallurgy is followed by normal shift assaying. For various periods the selectivity in the Cu–Pb flotation for Cu and Pb against Zn and pyrite has been disturbed by reuse water. It has been possible, however, to correlate such disturbances to extreme water compositions with low pH and increased Cu ion content caused by malfunctions in the lime dosage system for tailings.

It is planned to maintain the reuse loop throughout 1980 to enable long-term changes and seasonal impacts to be followed.

Summary

The practice and experience of reuse reported here are based on a few examples only. Generalized conclusions are hard to draw because of widely differing local conditions. With this in mind the most important experiences, mainly from external reuse, can be summarized as indicated below.

Reuse is practised to some extent in all the concentrators described.

The reuse percentage is, in some cases, limited by precipitation phenomena in pipes and spray nozzles. More often, however, the reuse percentage appears to be limited by adverse effects on the floatability of the minerals.

Lead–zinc ores of minimal mineralogical complexity have shown extreme sensitivity to reuse water addition to the final grinding and the flotation circuits. The harmful influence on lead concentrate grade is dramatic. Copper–zinc–pyrite ores have shown a deterioration when reuse water has been employed in the final grinding and flotation circuits. Lower recoveries of copper and zinc have been reported. Pyrite circuits, however, seem to tolerate reuse water addition. Extensive reuse is accompanied by highly unstable process performance, specifically in the zinc circuits. Because of the harmful influence of reuse water in the final grinding and flotation circuits its use has been restricted, in the main, to primary grinding (as a mixture with fresh water), pyrite flotation, dilution of tailings before backfill cycloning and other dilution and cleansing applications where its influence on flotation is negligible.

To study the mechanisms involved, and particularly the metallurgical implications of water reuse, comprehensive work is being undertaken by the central research body and the mining companies.

Acknowledgment

The author wishes to thank the management of Boliden Mineral AB, Bolaget Vieille Montagne and Stora Kopparbergs Bergslags AB for their kind permission to publish data on the operations described in the paper. The author also addresses his thanks to the Swedish Mineral Processing Research Foundation—MinFo—for its permission to include a presentation on one of its research projects.

The author is indebted to the following for generous assistance in the preparation of the paper: R. Maripuu and T. Göransson, both of Boliden Mineral AB, F. Mellberg of Bolaget Vieille Montagne and O. Albertsson and T. Larsson, both of Stora Kopparbergs Bergslags AB. Miss B. Vaughan Jones is acknowledged for her assistance in the translation.

FULL SCALE TEST OF PROCESS WATER REUSE IN A COMPLEX SULPHIDE ORE CIRCUIT

K.S.E. FORSSBERG[1], H.R. JONSSON[2] and B.I. PALSSON[1]

[1] Division of Mineral Processing, Luleå University of Technology, S-951 87 Luleå (Sweden)

[2] Formerly Division of Mineral Processing, Luleå University of Technology, now with LKAB, S-971 00 Malmberget (Sweden)

ABSTRACT

Full scale tests involving reuse of water from a tailings pond have been performed on two occasions with the same ore. The tests were made before and after the pond froze over in order to determine whether reduced oxygen supply has any effect on the sulphur anion concentration in the water, and how this and other factors affect the flotation process. Anions were analyzed by ion chromatography, which enables unstable sulphur anions to be detected quickly.

The tests showed that the greatest problem during short periods of water reuse is that the froth layer alters its nature in a way that makes it difficult to control the flotation process and creates practical problems with regard to pumping the froth. Further tests will have to include some means of analyzing suspended colloidal and organic matter, among other things, to find out what happens to the froth layer. The tests should also cover a longer period of time to enable observation of any long-term effects.

INTRODUCTION

As a result of pressure on the mining industry to start recycling its process water on a larger scale with a view to reducing water pollution from mines and concentrators, the Swedish mining industry, both under its own auspices and through the Swedish Mineral Processing Research Foundation (MinFo), has invested in an extensive program of systematic reclamation trials at a number of concentrators in Sweden. These trials involve the use of modern analytical techniques in an effort to follow pulp chemistry events as closely as possible when the source of process water changes.

Detailed pulp chemistry data from flotation circuits in Australia have been published by Woodcock & Jones (ref.1,2,3,4). The emphasis of their investigations was on metals in solution, pH, redox potential, O_2(aq), residual reagent concentrations, and concentrations of free and complexed cyanide. Other anions were not investigated, except with regard to the influence of sulphite dosage on O_2(aq) and redox potential.

Studies of the effect of sulphur anions (ref.5) on the flotation properties of sulphide mineral have been made in Norway. These studies were mainly concerned with the formation of thiosulphate as a function of pH, oxygen supply,

temperature, reaction time and particle size. Both laboratory, pilot scale and full scale tests were performed. The results indicate that the thiosulphate content of the pulp can have a disturbing effect, especially on copper activation of sphalerite.

A general description of water recycling experiments performed by a number of mining companies at concentrators in Sweden has already been published (ref. 6). It also includes preliminary results of the MinFo-supported experiments at Stora Kopparbergs Bergslags AB's concentrator in Falun. A more detailed account of the latter has since been published (ref.7).

The Division of Mineral Processing of the Luleå University of Technology has been commissioned by the MinFo to work on MinFo Project No. 15, "Circulation and Purification of Process Water". Some of the experiments have been performed at Boliden Mineral AB's concentrator in Kristineberg. In consultation with Boliden Mineral AB it was decided to run water reuse trials with Näsliden ore; this is a complex sulphide ore with high pyrite, pyrrhotite and arsenopyrite grades, so high concentrations of thiosulphate could be expected. Average assays of Näsliden ore are 1.4 g/t Au, 36 g/t Ag, 1.1% Cu, 2.9% Zn, 0.3% Pb, 1.3% As and 28% S.

The present paper reports the results of pulp chemistry measurements in experiments with water reuse in the external loop during Näsliden ore campaigns in October 1982 and April 1983. The object of the first campaign was to trace the concentration of sulphur anions with an ion chromatograph during a brief water recycling experiment. A secondary objective was to obtain background data for future measurements.

The experiments in April 1983 were a repetition of the earlier water recycling experiment. In October the tailings pond was free from ice, so availability of dissolved oxygen in the water was good. It was therefore interesting to repeat the experiment at a time when the pond had been covered with ice for 4-5 months to see if the shorter oxygen supply affected pulp chemistry conditions in any way. In theory the oxidation of sulphite, thiosulphate and polythionates should slow down when the pond is ice-covered, which would mean that the concentrations of these ions in the reused water ought to be higher during the winter than in the summer and autumn.

DESCRIPTION OF THE PLANT

The Kristineberg concentrator processes about a million tonnes of ore annually from the mines at Kristineberg, Näsliden and Rävliden. The ore is graded into five qualities, which are processed campaignwise in the two sections of the plant. Annual output comprises 35 kt copper concentrate, 65 kt zinc concentrate, 5 kt lead concentrate and 110 kt pyrite concentrate.

The water recycling experiments were performed in Section A of the plant. This is described briefly below; see also the outline flowsheet in Fig. 1.

Fig. 1. Kristineberg concentrator, simplified flowsheet. Circled numbers show sampling points

Primary grinding takes place in two parallel rod mills, and secondary grinding in a pebble mill in closed circuit with a hydrocyclone. Pulp is fed back from copper flotation to the mill circuit for regrinding. Milk of lime is added to the rod mill feed to adjust the pH to 11-12. There is no actual regulation of pH; the lime dosage is a fixed proportion of the total amount of lime supplied to the section.

Copper-lead flotation is divided into two rougher stages, one scavenger stage and five cleaner stages. Flotation is performed at pH 11.3 (milk of lime) with amyl xanthate as the collector and pine oil as the frother. Zinc sulphate and sodium bisulphite are added in the cleaner circuit to depress zinc. If the lead grade in the copper-lead concentrate exceeds 10-15% by mass, the concentrate is diverted to a separation circuit where lead is depressed with bichromate and copper is floated.

Zinc flotation comprises rougher and scavenger stages and five cleaner stages. The rougher concentrate is reground in a smaller ball mill. The zinc mineral is marmatite containing about 9% Fe; it is activated with copper sulphate and then floated at pH 11.5 with isopropyl xanthate as the collector and pine oil as the frother.

Pyrite flotation is performed on two of the five qualities of ore. No further description is given here because the experiments were performed with Näsliden ore, which does not undergo pyrite flotation.

Water samples were taken at four points for chemical analysis and surface tension measurement: feed water to the pebble mill, discharge from rod mill

No. 2, Cu-Pb flotation middlings, and Zn flotation middlings. On-the-spot measurements of pulp pH, redox potential and temperature (April campaign only) were also made at these points. One set of samples was taken in the morning, and another in the afternoon. It took about four hours to collect and analyze a set of four samples.

In these experiments the section was initially run on fresh water only, reuse water from the tailings pond being subsequently piped into the water supply to the section. Fresh water was however used throughout for dilution of the hydrocyclone feed and the liquid seals of the horizontal pumps. The proportion of recycled water was therefore never more than about 75% of the total volume of process water in the section.

EQUIPMENT FOR SAMPLING AND ANALYSIS

Sampling equipment

Sampling for anion determination, especially for determination of unstable sulphide, sulphite and thiosulphate ions, makes heavy demands on equipment and technique. The equipment must allow the samples to be taken quickly, and the samples must be protected as far as possible against oxidation until they are transferred to analytical instruments. The sampling equipment was assembled from standard Millipore(R) components (see Fig. 2).

Fig. 2. Equipment for quick sampling of mineral pulp.
1. Sampling hose, 100 mm
2. Plastic filter holder, ø 25 mm, with wire gauze strainer (found by later experiments to be unnecessary)
3. Plastic filter holder, ø 25 mm, with 8 micron membrane filter
4. Plastic two-way valve
5. Plastic sampling syringe (pump), 50 ml
6. Plastic hose connector, ø 4 mm
7. Disposable plastic filter, ø 25 mm, 0.22 micron
9. Disposable syringe, 2 ml

Suitable quantities of mineral pulp samples were taken with a dipper and transferred to a 5-litre plastic pail. After brief sedimentation (<5 min), a

sample of 2-10 ml was sucked from the top layer of pulp in the pail. A separate sample was then taken from the pail and filtered for surface tension measurement and cation analysis.

The filter holder with the wire gauze strainer was removed for sampling of process water feed; the sample was sucked straight from the dipper and the quantity obtained in this way, about 50 ml, was used for ion chromatography, surface tension measurement and cation analysis.

Samples for cation, total sulphur and bicarbonate analysis and for surface tension measurement were filtered through an OOR filter and then through a 1.2 micron membrane filter.

The elapsed time from collection to injection into the ion chromatograph was 5-10 minutes for feed water samples and 10-15 minutes for pulp samples.

Surface tension measurements

Surface tension was measured with a Krüss Du Noüy ring balance. The platinum ring was rinsed in distilled water and heated in the flame of a methanol burner between measurements. The glassware was cleaned by boiling in distilled water.

Two measurements were made on each sample; tables and figures show mean readings. It may be noted that in the October campaign the second reading of a sample was consistently higher than the first. This is probably attributable to contamination with methanol (purum) from the spirit burner. Methanol (p.a.) was used in the April campaign, and this cured the problem.

After the surface tension measurements the same sample was poured into 100 ml flasks for analysis of cations, etc. This was done during the October campaign only, the reason being that filtration capacity was limited. Use of the spirit burner may therefore have contaminated the samples, but any contaminants were organic and would not have affected the analysis of inorganic substances.

pH, redox potential and temperature measurements

These measurements were made on the spot in the pulp flow, as the redox potential of the pulp rises sharply if the sample is exposed to air. It is likewise important that the measurements are made on unsedimented pulp samples. Elapsed time between sampling for anion analysis and redox measurement was 10-15 minutes. Temperatures were also measured during the April campaign.

The readings were taken with a battery-powered Radiometer PHM 80 pH meter. The GK2401C combination electrode was used for pH measurements, and the P101 platinum electrode together with the K401 calomel electrode for potential measurements.

Before each measurement the platinum electrode was carefully wiped clean with a moistened paper polishing cloth sprinkled with Al_2O_3 powder. The calomel electrode was calibrated daily against a similar electrode stored in the same

way as the one used for measurements. The difference in potential never exceeded 3 mV. Potential readings were corrected for the normal potential of the calomel electrode (+245 mV at 25°C).

Prior to pH measurements the pH electrode was checked against a suitable buffer solution. Two buffer solutions of pH 9 and 11 respectively were used, the former for process feed water measurements.

Ion chromatography

Samples were sucked into the large syringe (see Fig. 2). In the laboratory the disposable filter was attached and the sample was expelled into the disposable syringe, which was then removed and placed in the sample port of the ion chromatograph, after which the sample (approx. 0.5 ml) was injected.

The ion chromatograph, a DioneX 2010i, is equipped with a system of columns for anion analysis and two detectors, one electrochemical and one conductometric. The relative positions of the columns and detectors are shown in Fig. 3. The sensitivity of these detectors varies according to the type of ion; sulphide and thiosulphate ions are most readily detected by the electrochemical detector, while other anions were determined with the conductometric detector. The principles of ion chromatographic analysis of inorganic anions and cations are described in ref.8.

Fig. 3. Simplified representation of an ion chromatograph.

The output signals from the detectors were fed to integrators, which computed concentrations on the basis of peak areas with reference to known standard samples. During the October campaign an ordinary chart recorder and manual computation from peak heights were used for the conductometric detector. Time between samplings was governed by the time taken by the ion chromatograph (50-60 minutes) to analyze all the ions in a sample. With samples that do not contain thiosulphate this time can be shortened to 10-15 minutes.

Analysis of bicarbonate concentration

This was done during the April campaign only. The concentration of bicarbonate (HCO_3^-) was obtained by titration of a filtered (1.2 micron) sample with 0.05 M hydrochloric acid. The distance between the inflection points on the titre curve gave the HCO_3^- concentration.

Cation and total sulphur analysis

Analyses of the total concentrations of Cu, Pb, Zn, Fe, Ca and S in the samples were performed at Boliden Metall AB's Rönnskär laboratory. Filtered (1.2 micron) samples of about 100 ml were prepared for the purpose during the October campaign. One-litre samples were used in the April campaign. The samples were acidified with nitric acid to prevent precipitation of metallic hydroxides. Filtered samples in 100 ml flasks were sent for analysis of S_{tot} (as sulphate in oxidized sample).

RESULTS

Method

The October campaign lasted from 8 to 16 October inclusive; sampling began on 11 October. For an initial reference period up to and including 13 October the mill and flotation circuits were operated on fresh water only. At 0615 hours on the morning of 14 October the water supply system was reconnected to deliver reuse water from the tailings pond to the whole of Section A of the concentrator.

The April campaign began with the switch to Näsliden ore at 2155 hours on 5 April. Fresh water only was supplied to the mill and flotation circuits for a reference period lasting until 0645 hours on 8 April, when reuse water from the tailings pond was piped to the water supply system of Section A. The reuse test ended at 1230 hours on 11 April, when the fresh water supply to the system was reconnected. Sampling continued until the following day with a view to observing any transitional effects.

Pulp chemistry measurements

Detailed results of anion analysis, cation analysis, S_{tot}, and measurements of surface tension, redox potential and pH are reported elsewhere with place, time and date of sampling (ref.9,10).

The most interesting analytical results and figures derived from them are presented graphically in Figs. 4-20. These graphs have a common time axis; readings from the first round of samplings are plotted against the date, and readings from the second round against the date +0.5. (Sampling took place in the morning and afternoon.)

Fig. 4a. pH variations during October campaign.

Fig. 4b. pH variations during April campaign.

The pH measurements show that changes in the pH of the feed water to the process have hardly any effect on other points (see Fig.4a&b). Indeed, no such effect is to be expected, as flotation takes place in a lime alkaline environment with pH regulation. The slight rise in pH in the Cu-Pb flotation middlings during the October campaign can be attributed to the better process monitoring that is always found in the first few days of full scale operational trials.

Redox potential readings at various points in the process show only that the redox potential of the process water has no appreciable influence (see Fig. 5a&b). There is of course a difference between measurement conditions in that the process water measurements were made in a particle-free system, whereas the other readings were taken direct from pulp. Consequently, it is not certain whether the pulp readings represent actual redox potentials (Eh) or mixed potentials, which are only comparable within the same system. For practical purposes we consider that the potential difference (Pt/S.C.E.) gives us the redox potential.

Fig. 5a. Eh variations during October campaign.

Fig. 5b. Eh variations during April campaign.

The best way to compare Eh and pH readings taken in non-uniform conditions is to plot them on Eh/pH graphs (see Fig. 6a&b). From these we can see that the various process points are well grouped and that there is no difference between readings taken during use of fresh and recycled water.

Fig. 6a. Eh/pH graph for October campaign.

Fig. 6b. Eh/pH graph for April campaign.

Process temperatures were stable during the period of sampling (in April). Mean readings are listed in Table 1.

TABLE 1

Temperatures at process sampling points during April campaign.

Process sampling point	Temperature (°C)	
	Fresh water	Recycled water
Feed water to pebble mill	1.5	2.7
Discharge from rod mill No. 2	13.2	14.8
Cu-Pb flotation middlings	12.2	13.3
Zn flotation middlings	11.7	13.0

The chloride concentrations in the recycled water were about five times higher than in the fresh water (see Fig. 7a&b). This was partly reflected in the other sampling points, where the background level was somewhat higher.

The graphs show that the principal chloride source is the ore or substances associated with it. Concentrations in the rod mill discharge were twice as high during the April campaign as in the October campaign. This is probably because calcium chloride had been added to the ore during handling to avoid freezing problems in ore bins and chutes.

Fig. 7a. Chloride concentrations during October campaign.

Fig. 7b. Chloride concentrations during April campaign.

Thiosulphate concentrations display a clear pattern for the October campaign, being lowest in the rod mill discharge, highest in the Cu-Pb flotation middlings, and down again somewhat in the Zn flotation middlings. The switch to recycled water produced only a marginal rise of thiosulphate concentrations in the process. During the April campaign the concentrations in the recycled water

were higher, resulting in a greater influence on the thiosulphate level in the process. No acceptable explanation has been found for the sharp rise and fall of concentration at the beginning of the April campaign.

Fig. 8a. Thiosulphate concentrations during October campaign.

Fig. 8b. Thiosulphate concentrations during April campaign.

The sulphite concentrations show that it makes no difference in this respect whether fresh or recycled water is used (see Fig. 9a&b). The pattern of relative variations of sulphite concentration is the same as for thiosulphate - highest in the Cu-Pb flotation middlings and lowest in the rod mill discharge. Only during the recycling period of the April campaign was any sulphite detected in the process water feed.

Fig. 9a. Sulphite concentrations during October campaign.

Fig. 9b. Sulphite concentrations during April campaign.

The sulphate present in the recycled feed water shows up at the other sampling points (see Fig. 10a&b). Concentrations during the October campaign were generally higher than during the April campaign; the analyses from the October campaign also show that the sulphate content of the pulp liquid can vary widely even during periods of fresh water use.

Fig. 10a. Sulphate concentrations during October campaign.

Fig. 10b. Sulphate concentrations during April campaign.

Fig. 11a. Calcium concentrations during October campaign.

Fig. 11b. Calcium concentrations during April campaign.

The calcium concentrations in the process are highest in the rod mill discharge, and at about the same level in the middlings from both Cu-Pb and Zn

flotation (see Fig. 11a&b). The calcium concentration was very high on the last day of the October campaign. This was because the lime dosage to the rod mill was too high; at the time of sampling the pH was 12.0. It is further evident that the switch to recycled water was most clearly reflected in the rod mill discharge; the effect at other points in the process was small.

As both the calcium and sulphate concentrations show wide variations, it ought to be of interest to see whether this might be due to precipitation reactions in the pulp. To find out wheter such is the case, the ion product between calcium and sulphate was calculated (see Fig. 12a&b) and compared with the figure calculated from the known solubility of gypsum ($CaSO_4*2H_2O$), which is 2.41 g/l at 25°C (ref.11). Only at the point of discharge from the rod mill in the October campaign was there any risk that the recycled water might cause precipitation of gypsum in the pulp. Otherwise the ion product figures for the middlings are remarkably closely grouped.

Fig. 12a. Ion product $Ca*SO_4$ during October campaign.

Fig. 12b. Ion product $Ca*SO_4$ during April campaign.

Fig. 13a. Total sulphur concentration during October campaign.

Fig. 12b. Total sulphur concentration during April campaign.

To check whether the analyses of sulphur anions were realistic, S_{tot} was also determined by a wet chemical method (see Fig. 13a&b). The analyses show that the higher concentration in the recycled water shows up at the other points in the process. Otherwise it is surprising that the S_{tot} concentrations at the various points in the process are as closely grouped as they are. A comparison with S_{tot} calculated from sulphate, sulphite and thiosulphate shows that the figures obtained by analysis are sometimes higher than the calculated figures and sometimes lower.

In the April campaign the ion chromatograph had been adjusted so that it could also analyze for nitrate (see Fig. 14). Nitrate analysis is complicated by the fact that the nitrate and sulphate peaks are eluted close to each other on the ion chromatogram, which means that high sulphate concentrations can mask smaller nitrate concentrations. The nitrate obviously originates from blasting explosive residues (ammonium nitrate) in the ore.

The bicarbonate concentration at the sampling points (see Fig. 15) was also determined during the April campaign. The concentrations vary widely, but it is evident that while the concentration is significantly higher in recycled water than in fresh water, the difference does not show up at downstream points in the process.

Fig. 14. Nitrate concentrations during October campaign.

Fig. 15. Bicarbonate concentrations during April campaign.

In the course of the October campaign it was found that the sample volumes were too small to give low enough limits of detection for metals in solution. Only zinc was consistently above the limit of detection. The metal concentrations reported below (Figs. 16-19) therefore refer to the April campaign only. Metal concentrations at the sampling points were not affected by the origin of the process water. The peaks that occur are generally attributable to changes in pH.

Fig. 16. Copper concentrations during April campaign.

Fig. 17. Lead concentrations during April campaign.

Fig. 18. Zinc concentrations during April campaign.

Fig. 19. Iron concentrations during April campaign.

Fig. 20a. Surface tension during October campaign.

Fig. 20b. Surface tension during April campaign.

The surface tension measurements (see Fig. 20a&b) cannot account for the frothing problems that arose during use of recycled water from the tailings pond as process water. It was noted, however, that the reading were lower in the October campaign than in the April campaign. The great variations in the former can possibly be ascribed to the experimental problems mentioned earlier.

Process results

The process results are reported in detail elsewhere (ref.9,10). No dramatic effects of the differences in process water quality can be traced in the daily beneficiation statistics. The greatest problem was that the froth tended to "run" in the cleaner stages, though this is not directly reflected in the analyses of the concentrates. Consequently only the Cu-Pb concentrate grades (Fig. 21a&b) and the grade/recovery ratios for the Zn concentrate (Fig. 22a&b) are given here.

Fig. 21a. Grades of Cu-Pb concentrates during October campaign.

Fig. 21b. Grades of Cu-Pb concentrates during April campaign.

A certain switching effect can be detected from the daily analyses in Fig. 21 . The copper grade in the concentrate is slightly lower the day after the switch to reuse water, but this is compensated by an increase in copper recovery. To compensate for the runny froth layer and its adverse effect on selectivity, the frother dosage was reduced to about half the normal amount. The most noticeable effect of the switch is the rise in the Pb grade of the Cu-Pb concentrate during the October campaign.

The switching effect is also noticeable in the zinc concentrate (see Fig. 22a&b). The process disturbance was greater here than in the Cu-Pb flotation, and so were the problems with runny froth in the cleaner stages.

Fig. 22a. Grade/recovery ratios of Zn concentrate during October campaign.

Fig. 22b. Grade/recovery ratios of Zn concentrate during April campaign.

DISCUSSION

Sampling, October 1982

Pulp chemistry measurements detected thiosulphate concentrations ranging from 200 to 400 mg/l, so the comparatively low concentration in the recycled water did not show up in measurements at points downstream.

It should be noted that the reference samples of Kristineberg ore pulp taken in Section B during the October campaign show lower concentrations of thiosulphate than the corresponding samples of Näsliden ore pulp (see Table 2). This means that the concentration of unstable sulphur anions depends on the nature of the ore, which suggests that different ores have different levels of tolerance for such parameters as the thiosulphate content of the process water.

TABLE 2

Pulp chemistry data on Kristineberg ore in Section B.

Sampling point	pH	Sulphur anions (mg/l)		
		Thiosulphate	Sulphite	Sulphate
Discharge from rod mill	11.0	160	6	1200
Cu-Pb flotation middlings	11.6	230	52	810

There is a clear correlation between the sulphate concentration in the process feed water and the sulphate levels in the concentration process. Only at the discharge from the rod mill do conditions for precipitation of gypsum exist. At the other analysis points the value of the ion product is governed by some other complexing or precipitating reaction. The reaction in question is probably between calcium and carbonate, the latter originating from dissolved atmospheric carbon dioxide.

The sulphite concentration was consistently lowest at the discharge from the rod mill, with the exception of process water in which sulphite could not be detected. The limit of detection was about 1 mg/l.

Despite repeated attempts it was not possible to detect sulphide, S^{2-}, in any of the samples. Here again the limit of detection was about 1 mg/l. It is possible that the metallic copper gauze used in the prefilter may have precipitated any sulphide ions that were originally present, but this seems unlikely, as no sulphide ions were detected either when the prefilter was not used.

The process was relatively little affected from the metallurgical point of view by the used of recycled pond water. The effect that was noticed first was increased frothing in the cleaner stages with a consequent drop in selectivity. This was however corrected by a reduction in the frother dosage.

The results for the Cu-Pb flotation indicate that recoveries of copper, gold and silver were the same during the reuse period as when fresh water was supplied to the process. The most apparent effect was a rise of about one percentage unit in the Pb grade of the Cu-Pb concentrate.

Another noticeable effect of the use of recycled water was the formation of a hard-to-pump froth in connection with pulp X-ray analysis. The return pumps had to be restarted several times to prevent the sumps from overflowing.

Sampling, April 1983

The pulp chemistry measurements show that both sulphite and thiosulphate concentrations in the recycled water were higher during the campaign in April 1983 than in the one in October 1982. The probable reason for this is that at the time of the April campaign the tailings pond had been frozen over for five months, and the oxygen content of the water was therefore low. It is unlikely that the temperature of the recycled water, i.e. of the tailings pond, had any significant effect on the concentration of thiosulphate, as the October measurements were made just before the pond froze over.

The stable level of the thiosulphate concentration in the recycled water was about 80 mg/l compared to 50 mg/l in October. The effects of the switch to recycled water were therefore more noticeable in April.

The sulphate concentration in the recycled water was lower than in October. This was likewise due to the shorter oxygen supply in the tailings pond. There

was no risk of gypsum precipitation at any of the sampling points, even though the sulphate concentration rose considerably in the process when the reuse water was connected.

The bicarbonate concentrations indicate that there is also some carbonate activity in the pulp - probably a reaction between calcium and carbonate to form calcium carbonate. This compound will act as a calcium trap in the process, an assumption supported by the fact that only exceptionally does the ion product $Ca*SO_4$ reach the gypsum precipitation level.

Once again, the metallurgical effect of recycled water on the process was relatively small. There was however a tendency to a lower Cu grade in the Cu-Pb concentrate, though Cu recovery was unaffected. In addition, the recovery of zinc was somewhat higher, but the concentrate grade somewhat lower, during the recycling period. These observations are probably connected with the frothing problems that arose when reuse water was supplied to the process. Traditional surface tension measurements failed once again to detect any difference between periods of fresh and recycled water supply.

No immediate difference could be detected when the process switched to using recycled water, but heavy frothing occurred in the cleaner stages after 6-8 hours, while the Cu-Pb rougher flotation remained unaffected. The dosage of frothing agent (pine oil) was then reduced to less than half, and this alleviated the frothing problem. Attempts to run the process without any frother at all were unsuccessful, as the Cu and Pb grades of the Cu-Pb flotation middlings rose immediately.

The large volumes of froth made it necessary to run both the regular and standby pumps in some of the pumping stages to prevent overflowing. The froth was finely divided and contained very little mineral. Similar problems were experienced in Zn cleaner flotation, especially in the final stages. The froth from the last Zn cleaner stage was also so hard that there was some difficulty in obtaining samples of Zn concentrate for X-ray analysis of the pulp. In the Zn circuit, too, some of the pumping stages had to be doubled up.

These difficulties with froth represent the major problem connected with short-term recycling experiments: one the one hand we get a runny, poorly mineralized froth, and on the other an over-stabilized froth. This indicates that the problems are caused by one or more surfactants which are not degraded in the tailings pond; alternatively, they may be degradation products of process reagents. It also appears that the oxygen supply in the tailings pond is significant, as the problems were much greater during the April campaign.

CONCLUSIONS

The following conclusions can be drawn from these trials:

1. The concentration of sulphur anions in the recycled water is at present so low compared to the normal level in the pulp that the additional amounts are unlikely to interfere with the flotation process.
2. The use of recycled pond water gives rise to great frothing problems in the cleaner stages, probably as a result of insufficient degradation of frothers and collectors in the tailings pond.
3. The frothing characteristics of the recycled water ought to be investigated by registration of the height of the froth layer when air is blown through a column. This is only a relative method, but preliminary results indicate that it is much more sensitive than surface tension measurement.
4. As the immediate problems concerned the behaviour of the froth layer, future studies must be widened to include other methods of analysis. In particular, the content of suspended colloidal matter, the biological oxygen demand and the content of organic matter ought to be measured.
5. The studies should also include other types of ore.
6. Above all, the trials must be conducted over longer periods of time to enable detection of any cumulative effects in tailings ponds.

ACKNOWLEDGEMENTS

The authors would like to express their gratitude to the Swedish Mineral Processing Research Foundation for permission to publish results obtained in the course of work on the Foundation's "Circulation and Purification of Process Water" project.

The authors further wish to thank Boliden Mineral AB for allowing them to take measurements at the company's Kristineberg concentrator. Cordial thanks are also due to the personnel at Kristineberg for their unstinting help with the collection of measurement data.

Bertil Pålsson wishes to thank the staff of the CSIRO Mineral Engineering and Mineral Chemistry Divisions for thought-provoking and valuable discussions.

NICKEL-COPPER FLOTATION

Water management for Ni-Cu operations at Falconbridge at Sudbury and at Onaping mine-mill complexes and at INCO Metals, Copper Cliff Works is discussed in trip reports in Appendix I.

Although these trip reports primarily discuss effluents and tailings and macro site water management, one interesting observation was made at the Onaping operation. Here, the seepage from old tailings drains into the Fecunis Lake adjacent to an operating mill. Previously, the Fecunis Lake water containing nickel at levels above 10 mg/l used to drain into Moose Lake which forms part of the macro recycle and treatment system applied at Onaping. Through reversing the flow of Fecunis Lake water, it is now used as feedwater to the mill which operates at pH 10. At the high pH, Ni precipitates from solution. Consequently, by rearranging water flows, the need for a lime precipitation plant to treat Fecunis Lake water was avoided. In this case, the mill acts as a treatment plant, discharging the water ultimately with mill tailings from which it decants to Upper Moose Lake and ultimately to Lower Moose Lake with well below 1 ppm Ni^{2+}.

At Rustenburg there are several mines that produce a norite ore containing copper-nickel sulfide minerals associated with platinum group metals.

A former chemical treatment plant not belonging to any of the present mining companies operating in the area today used to discharge a sodium sulfate effluent to an unlined impoundment in this area. Apparently, this Na_2SO_4 solution seeped into the mineworkings and, on the way, leached magnesium from the pyroxonite rocks. When this minewater was used in the flotation concentrators, apparently problems resulted, e.g., higher reagent consumptions, etc.

During the 1983-1984 drought, great emphasis was placed on the need to save water, and more mill tailings water had to be recycled with the result that TDS levels built up. Concentrator metallurgists were making enquiries about how to overcome recovery deterioration effects which they ascribed to water quality, but not one of the operations would provide any information on these aspects for this report. Platinum recovery metallurgy details are considered company confidential in South Africa.

Trip reports on Falconbridge at Sudbury and at Onaping describe the intriguing integrated systems approach adopted by this company in their water management program. These are older mine-mill complexes, which started operations under a different set of environmental rules, but have innovatively adapted to meet the needs of the 1980's.

PHOSPHATE-COPPER

Phalaborwa-Foskor

Phosphate and copper minerals are recovered by flotation from a carbonatite ore at Phalaborwa, Transvaal, where two operators mine a huge deposit. Palaborwa Mining Company (Rio Tinto) recovers a copper sulfide concentrate and pumps their tailings across the fence to Foskor (Phosphate Development Corp.) which then recovers foskorite minerals. Foskor also teats 25,000 tps ore mined and stockpiled by PMC by crushing and grinding, followed by a sequential flotation of a copper sulfide concentrate and phosphate minerals followed by heavy mineral recovery of baddeleyite.

To operate these two flotation plants treating a combined total of 50,000 tpd ore, Foskor uses 28,000 m^3/d of "industrial water" to augment 22,000 m^3/d water received with the 25,000 tpd PMC tail stream. 50,000 m^3/d water enters the plantsite , and 39,800 is discharged to the creek as an effluent while 4,300 m^3/d is lost through evaporation. The "industrial water" is drawn primarily from the Olifants River seven km away.

A detailed water flow diagram and water balance is shown in the trip report on Phosphate Development Corp. in Appendix I.

In other words, Foskor uses about 28,000 m^3/d fresh water, and recycled water ammounts to about 22,000 m^3/d or 44% of total needs. Net water consumption works out to 1 m^3/t ore treated. Considerable quantities of water are internally recycled in the plant.

From a water management point of view, the most interesting aspect is the effect of high TDS on the flotation process and how it has been overcome through reagent addition. Foskor faces a water quality problem in that the 22,000 m^3/d water delivered with PMC tailings contains 5,100 ppm TDS of which 3,408 ppm is hardness. This water contains 1,260 mg/l Ca and 2,148 mg/l Mg as well as high concentrations of F^- (5.4 mg/l) and alkali metals. Concentration of SO_4 is 3,000 mg/l.

The trip report shows how water is recycled to various sections of the plant so that new water is used for milling and flotation of the ore crushed by Foskor, whereas reclaim water is used for treatment of the PMC flotation tailings from which, in turn, water is pumped to the tailings pond via a thickener to recover water which is recycled to a reclaim water dam.

Foskor has developed a flotation process which allows the poor quality water delivered with PMC tailings to be used.

However, testwork has shown that if 80% of the PMC water is replaced by fresh water, then a significant savings in reagents results.

Water quality effects are due primarily to interaction between the ore and water. Main gangue minerals in the PMC tails feed to Foskor are calcite, dolomite, phogopite, and olivine/serpentinites.

The hardness of the water interfers with the froth and reacts with the fatty acid collector used to float apatite to form Ca and Mg oleates. These are insoluble soaps and have a detrimental effect on the float system.

To overcome the effect on flotation, increased amounts of gangue depressant have to be used. In the primary flotation circuit, poly glycol ether is used as a gangue depressant. In the flotation plant treating PMC tails, poly glycol ether plus a modified polysaccharide is used.

Several types of poly glycol ethers have been tested. The one found to be most suitable is a nonyl-phenol tetra glycol ether. Polyglycol ether helps to emulsify the fatty acid and may adsorb on the calcite surfaces to help depress the gangue.

Chemically modified polysaccharide is supplied to Foskor by Trochem SA (Pty) Ltd. The modified polysaccharide is manufactured from guar beans and is known as Acrol LG 21 and Acrol LG 31. Typical doses are 120g per ton solids. Foskor's annual consumption of flotation reagents is confidential, but it is known to be "substantial," amounting to several million rands.

If clean water is used for flotation, a carboxylic acid derivative collector such as Hoechst 3309 has been indicated to work well and economically. However, with over 5,000 ppm TDS and such high hardness, the consumption of this experimental collector has been found to be excessive as it appears to be precipitated before it can get to the mineral.

Addition of waterglass Na_2SiO_3 has been found to act as a modifier/dispersant and also as a slight depressant for mica. Foskor uses about 600g waterglass per ton solids in their flotation reagent mix. Waterglass addition has also been found to remove some calcium and magnesium from solution.

Considerable testwork of flotation reagents and effects on and of ion populations in flotation pulps on flotation reagent consumption and recovery have been carried out by Foskor. The Council of Mineral Technology MINTEK carried out some considerable work on the same aspect of Foskor's flotation in the early 1970's as described by LOVELL, et al. (1971). Their work showed, amongst other things, that Foskorite recovery and selectivity of the flotation improved markedly with waterglass addition reaching a maximum at between 50 and 120 ppm Si in solution.

In the past, flotation difficulties in the main plant could sometimes be ascribed to a change in the raw water quality. The hardness of the industrial water fluctuated with

the seasons, reaching a peak before the first summer rains, and was shown to have an effect on apatite recovery from Foskorite.

The amount of suspended solids in industrial water, when the Olifants River was in flood, also was found to have an influence on apatite flotation, both in lab tests and in the plant.

Foskor investigated the roles of additional ions present in flotation plant water, and their interaction with ions from flotation reagents and from the mineral constituents of pyroxenite and foskorite ore, with particular emphasis on calcium and magnesium.

Several interesting observations were made:

1. Foskorite constituents, e.g., phlogopite, olivine, magnetite, calcite, and apatite all contributed ions to the water phase of the flotation pulp, and an alkaline pulp was obtained in each case.

2. Reagent additions to the ore pulp in dosages giving optimum apatite recovery constantly caused a removal of ions from the aqueous phase.

3. A significant removal of silicate ions was consistantly found. Soluble silicate was removed from solutions by gangue minerals calcite, and iron-bearing olivine, magnetite, and phlogopite, but not by apatite. Sodium silicate acts as a depressant of magnetite and olivine and lowers the iron content of apatite concentrates.

4. Very little flotation depression of calcite was observed in the absence of apatite although, in the presence of apatite, the same reagent combination gave excellent apatite-calcite separation and selective depression of calcite.

5. Once the mineral mixtures had been milled and conditioned with all essential flotation reagents, the flotation water could be filtered off and be replaced by demineralized water and the mineral subjected to flotation without any subsequent change in flotation recovery of apatite.

This latter discovery is a very significant observation, and it would be important to find out whether the same principles apply in any other cases--i.e., water quality in the mill has an important effect on the coatings on the mineral grains which determine flotation characteristics in this case.

EFFECTS OF REAGENTS AND ORE ON PULP WATER QUALITY

- Foskorite in different stages of weathering contributes calcium and magnesium to the system, and an alkaline pulp is always obtained.
- The reagents sodium hydroxide and sodium silicate soften the flotation liquid.
- Less reagents are necessary for successful flotation of apatite when demineralized water is used compared to industrial water.
- The order of addition of sodium silicate and sodium hydroxide affects the flotation recovery of apatite--soluble silicate reagent is removed from solution by the ore.
- Addition of sodium silicate and sodium hydroxide, either separately or together, caused a reduction in calcium and magnesium in solution in the pulps.
- Phlogopite contributes potassium, calcium, magnesium, and sodium to pulp solutions.
- Addition of NaOH to several mineral slurries resulted in a reduction in Ca and Mg that went into solution.
- Addition of calcium to a phogopite slurry resulted in an increase in potassium ions in solution.

ENVIRONMENTAL AND EFFLUENTS

Although flotation is a physical process, reactions between gangue and ore minerals and water or reagents can and does change the chemistry of the tailings effluent. In the case of Foskor, a high TDS and high F^- ion concentration at 3.9 ppm in tailings pond decant solution must be taken into account environmentally. A special dispensation from the Dept. of the Environment allows Foskor to discharge effluents to 4 ppm F^-.

PMC tailings water contains around 140 ppm K^+ which has been suspected of being a possible cause of a fishkill, but this has not been confirmed. Surprisingly, even though phosphate minerals are the principal value recovered, the level of PO_4^{3-} in recycled and effluent waters remains well below 1 ppm.

SCALE AND CORROSION

Despite very high TDS levels (3,500-5,500 ppm) with high Ca^{2+} (400-1,200 ppm) and SO_4^{2-} (1,500-3,000 ppm), which are well in excess of saturation, scale is not a problem

at Foskor. One possible reason for this is the very high Mg^{2+} (900-2,000 ppm) which seems to modify the solubility of $CaSO_4$, but no doubt other factors also play a role.

RECYCLING

The Foskor operation recycles large quantities of water, and the recycling flow pattern is relatively complicated as is shown in water balance diagram. Solution flows in two main recycling loops designed to keep the PMC tailings water out of the main Foskor flotation circuits while reclaim water is used to dilute the PMC tailings.

FLUORSPAR FLOTATION

Martin Wilson of U.S. Borax and Chemical Corp. was awarded U.S. Patent 4248708 dated February 3, 1981, which describes an improved process for treating water in fluorspar flotation circuits which substantially reduces slimes and interferring soluble materials, allowing the water to be recycled in the process and also improving its quality to make it suitable for discharge to the environment.

The process refers to a specific combination of coagulants and flocculants to obtain a clear recycle without adverse effects on fluorspar recovery allowing of in excess of 90% treated water.

The reagents used are a combination of a cationic polygalactomannan derivative as primary flocculant and a high molecular weight polyethylene oxide as a secondary flocculant. The polygalactomannans are polysaccharides composed of galacton and mannose units usually found in the endosperm of leguminous seeds such as locust beans, honey locust, flame tree, etc. Cationic derivatives of these are used for the water treatment process described by WILSON.

[57] ABSTRACT

Tailings slurry from fluorspar flotation is clarified and purified by sequential addition of a cationic polygalactomannan derivative and a poly(ethylene oxide).

10 Claims, No Drawings

PURIFICATION OF FLOTATION TAILINGS WATER

This invention relates to the clarification and purification of water from fluorspar flotation processes.

BACKGROUND OF THE INVENTION

Acid grade fluorspar (calcium fluoride) is generally obtained by means of a froth flotation procedure in which the fluorspar ore is ground and slurried with water, treated with flotation reagents and then submitted to a froth flotation procedure. The floated concentrate containing the calcium fluoride is recovered and may be submitted to further cleaner flotation steps. The tailings from the flotation procedure consist of silicates and carbonates which may be discarded or processed further for recovery of desirable products. A large volume of water is required in the process and, in the past, most fluorspar flotation operations did not recycle the water.

Fluorspar flotation is very sensitive to water quality since soluble salts may interfere with the flotation and reduce the grade and recovery of the product. Accordingly, only fresh and in many cases softened water is used in most fluorspar flotation operations. However, with increased concern for environmental contamination, it is desirable to recycle a large portion or possibly all of the process water used in such operations. In order to recycle the water, the tailings from the flotation procedure must be treated and clarified to minimize the build-up of slimes and interfering soluble compounds.

Various flocculating agents or coagulants such as aluminum sulfate and ferric chloride have been proposed for settling slimes in the tailings water from fluorspar flotation operations. However, since soluble salts build up in such water, they are usually unsuitable, either for recycle or discharge into the environment. Various organic polymers have been proposed as coagulants or flocculants for use in mineral processing and waste water treatment. For example, the use of polyacrylamides, polysaccharides, and flocculating glues is proposed in U.S. Pat. No. 3,138,550. High molecular weight ethylene oxide polymers were proposed by Manley, U.S. Pat. No. 3,141,816 as flocculants for removing fibers and other solid materials from waste water from paper making processes. Technical Service bulletins for POLYOX ethylene oxide polymers and JAGUAR C-13, a cationic guar derivative, recommend their use as flocculants in mineral processing.

SUMMARY OF THE INVENTION

There is provided by this invention an improved process for treating water obtained from a fluorspar flotation procedure in order to substantially reduce slimes and interfering soluble materials so that the water may be recycled in the process and further to improve the overall quality of the water so that, if necessary, some or most may be discarded without adverse effect on the environment.

The present invention provides a process utilizing a specific combination of coagulants or flocculants in order to obtain a significant improvement in tailings waters from a fluorspar flotation operation. By use of the combination of reagents of the present invention, one can obtain clear water which can be recycled in the flotation process with no adverse effect on the fluorspar metallurgy. Recovery and grade of fluorspar in subsequent flotation procedures, using an excess of 90% of the treated process water in recycle, is not significantly affected.

DESCRIPTION OF THE INVENTION

The present process employs a cationic polygalactomannan derivative as the primary flocculant and a high molecular weight poly(ethylene oxide) as a secondary flocculant. Polygalactomannans are polysaccharides composed principally of galactose and mannose units and are usually found in the endosperm of leguminous seeds such as guar, locust bean, honey locust, flame tree, and the like. The polygalactomannan derivatives employed in the present invention are cationic; that is, they have cationic substituent groups on the molecule. Such cationic groups may be formed by reaction of the polygalactomannan with a haloalkyl-substituted quaternary ammonium compound under alkaline conditions such as described by DeMartino in U.S. Pat. No. 4,031,307. The resultant quaternary ammonium ethers of polygalactomannan gum generally have a degree of substitution between about 0.01 and 3. Typical examples of such quaternary ammonium ethers are the trialkylammonium halide-alkenyl or alkyl-ethers such as the 4-(trimethylammonium chloride)-2-butenyl ethers of guar and locust bean gum. Other examples of cationic derivatives of polygalactomannan are disclosed in U.S. Pat. No. 3,467,647.

The high molecular weight polymers of ethylene oxide employed in the present process are non-ionic and generally have a molecular weight in excess of 200,000, preferably at least about 5 million. Such polymers are sold commercially by Union Carbide Corporation under the trademark POLYOX.

The flocculants are added sequentially to the tailings water with the cationic polygalactomannan composition being added first and then the poly(ethylene oxide) added second. The flocculants are conveniently added by means of dilute solutions in water, slowly with vigorous stirring. The solids are then allowed to settle and the clear supernatant liquid separated, such as by decantation.

The amount of cationic polygalactomannan composition added to the water to be treated is in the range of about 0.05 to 0.5 lb. per ton of ore (corresponding to about 0.1 to 1.0 lb. per ton of tailings solids) and the amount of polyethylene oxide is in the range of from about 0.005 to 0.1 lb. per ton of ore (corresponding to about 0.01 to 0.2 lb. per ton of tailings solids). A preferred ratio of polygalactomannan derivative to poly(ethylene oxide) is about 10:1.

The following examples are presented to illustrate the invention.

EXAMPLES 1-3

An aqueous slurry comprising the tails of a combined rougher and cleaner froth flotation of fluorspar was treated with reagents as described in Table I. The slurry to be treated (1600 ml.) had a specific gravity of about 1.25 and a pH of about 9.5. The slurries were first treated with the polygalactomannan derivative (JAGUAR C-13 0.1% solution) in three stages with about 1.5 minutes between each stage. The poly(ethylene oxide) (POLYOX 0.1% solution) was then added at the end of the third stage. The treated slurry was allowed to settle and the settling rate was recorded. The clarity of the cleared liquor was also determined by a turbidity meter after 5 and 10 minutes, as well as the amount of solids remaining in 50 ml. of the cleared liquor after 10 minutes. The following results were obtained.

TABLE I

Ex.	1	2	3
JAGUAR (lb/ton ore)	0.12	0.12	0.12
POLYOX (lb/ton ore)	0	0.012	0.012
Settling rate (ft./hr.)	93.7	120.5	105.5
Clarity - 5 min. (NTU)	63	18	32.5
Clarity - 10 min. (NTU)	51	12	32
Solids (clear liquor) (ppm)	100	16	18

EXAMPLES 4-8

The procedure of Examples 1-3 was repeated except 100 ml. of slurry was used in the test. The following results were obtained.

TABLE II

Ex.	4	5	6	7	8
JAGUAR (lb/ton ore)	0.24	0.24	0.16	0.20	0.32
POLYOX (lb/ton ore)	0	0.024	0.016	0.02	0.032
Clarity - 10 min. (NTU)	64	29	56	44	23
Solids (clear liquor) (ppm)	63	4	15	5	2

Various changes and modifications of the invention can be made, and, to the extent that such variations incorporate the spirit of this invention, they are intended to be included within the scope of the appended claims.

What is claimed is:

1. The method of purifying and clarifying a basic aqueous flotation tailings slurry which comprises sequentially adding first a cationic polygalactomannan flocculant and then a non-ionic poly(ethylene oxide) flocculant to said slurry, allowing the solids to settle and separating the purified and clarified liquor from said settled solids.

2. The method in accordance with claim 1 in which said poly(ethylene oxide) has a molecular weight in excess of 200,000.

3. The method according to claim 2 in which said poly(ethylene oxide) has a molecular weight of at least about 5 million.

4. The method in accordance with claim 1 in which said cationic polygalactomannan is a quaternary ammonium ether of polygalactomannan.

5. The method in accordance with claim 1 in which said tailings slurry is from a fluorspar froth flotation.

6. The method according to claim 5 in which said cationic polygalactomannan is a quaternary ammonium ether of polygalactomannan.

7. The method according to claim 5 in which the weight ratio of said cationic polygalactomannan to said poly(ethylene oxide) is about 10:1.

8. The method in accordance with claim 1 in which about 0.1 to 1 pound of said cationic polygalactomannan and about 0.01 to 0.2 pound of said poly(ethylene oxide) is added per ton of solids in said tailings slurry.

9. The method in accordance with claim 8 in which the weight ratio of said cationic polygalactomannan to said poly(ethylene oxide) is about 10:1.

10. The method in accordance with claim 9 in which said flotation tailings slurry is a basic aqueous slurry from a fluorspar froth flotation, said cationic polygalactomannan is a quaternary ammonium ether of polygalactomannan and said poly(ethylene oxide) has a molecular weight of at least about 5 million.

SEAWATER IN FLOTATION

In locations where an adequate supply of fresh water is not available, it has at several locations become necessary to use seawater in flotation mills. Examples of these locations are:

- An operation in Ireland, possibly Tynagh (?).
- Copper precipitate flotation on the Peruvian coastline
- Texada Mines, Texada Island, British Columbia
- Pennarroya-Mediterranean Operations:
  - -- Carthagene (Spain), Pb-Zn
  - -- Argentiera (Sardinia), Pb-Zn (Closed in 1963)
  - -- Laurium (Greece), Pb-Zn
  - -- Ain Barbar, Cu-Pb-Zn
- Cominco-Greenland
  - -- Greenex, Cu-Pb-Zn

COMPOSITION OF SEAWATER

Typical seawater contains 35,000-45,000 mg/l TDS made up of:

Constituent	mg/l
Cl^-	19,000
Na^+	10,500
$SO_4^=$	2,700
Mg	1,350
Ca	400
K	380
HCO_3^-	142
Br	65
Sr	8
SiO_2	6
B	5
F^-	1.3

There are considerable differences in the inorganic composition of seawater, depending on geographic location. For example, the Red Sea has a higher TDS content than the Atlantic Ocean.

There are also significant differences in the organics content of inshore seawater from site to site. For exsmple, efforts to desalinate seawater from the South West African

coastline failed due to a suspension of homogenized organic constituents in the water, possibly the remnants of plankton biomass or surf homogenized seaweeds, etc. Such species could well also be expected to interfere with flotation processes if they were present, even if only in dissolved oxygen denudation.

SPECIAL CONDITIONS FOR SEAWATER FLOTATION

When seawater is used in flotation, the corrosiveness of the highly saline water must be taken into account. Special materials must be used for pumps, pipes, and tanks, etc.

According to COMINCO technical staff, sulfide minerals float well in seawater as long as the minerals are treated as rapidly as possible. That is, contact of a short duration with seawater has a minimal effect on the floatability of mineral grains but after an extended period of time, an effect is noted as the surfaces of the mineral grains start reacting. Cominco Ltd. staff had no further details to offer about the Greenex project, but Randol is grateful to them for providing the two papers inserted below. Mike Smith, who worked on this project startup for BECHTEL CORP., recalls that the key to successful operation was found once a good froth could be generated. He can be reached as follows:

Apparently, ENAMI was involved in Cu precipitate flotation plants in Chile. A Dow collector Z-200 was preferred in this case because the conventional crysilic acid frother, although less expensive, did not give a good froth in seawater.

Interesting details are included in the following reports by REY, et al. (1966) and HAIG (1974) inserted below.

Dear Dr. Michaelis:

My review of "the use of salt water in flotation circuits" was presented orally only and was not completed in a form suitable for publication. I believe that a good review of the theory and operating experiences of salt water flotation would still be a meaningful contribution but it is currently on the "back-burner" for me to complete.

Sincerely,

George W. Poling

FLOTATION OF ORES IN SEA-WATER

February - 1966

Milling plants bordering the sea sometimes use sea-water when fresh water is not available in sufficient quantity.

Our purpose is to describe the characteristics of this type of flotation and to indicate the measures which must be taken in the construction of these mills to avoid excessive corrosion.

Application of Sea-Water

Sea-water, like strongly saline solutions, has a high frothing power. On the other hand, it increases the water repellency of minerals, such as sulphur, graphite, coal, and talc, which show natural floatability (1). It has even been proposed to clean coal by floating it in sea-water without any reagent addition (2).

Sulfides and native metals are easily floated in sea-water by soluble collectors such as xanthates. This is how, around 1930, Tocopilla Mining Company in the north of Chile floated a chalcopyrite ore (3).

Differential flotation is also practised, but it is, as a rule, a little more delicate than in fresh water. Several examples are mentioned in publications (4) (5). Société Minière et Métallurgique de Peñarroya and its subsidiary, Société de Pertusola, use or have used sea-water alone or with fresh water in mills around the Mediterranean.

These mills are the following :

Carthagene (Spain)	Pb-Zn ore
Argentiera (Sardinia)	Pb-Zn ore (until 1963)
Laurium (Greece)	Pb-Zn ore
Ain Barbar (Algeria)	Cu-Pb-Zn ore
(see annexed map)	

Flotation of oxidized ores is more difficult than flotation of sulphides. Oxidized lead ores can be sulphidized with sodium sulphide, but conditions are apparently more delicate than in soft water. This operation has been practised occasionally in the mills of Société de Peñarroya, but the study has not been pushed far enough to draw conclusions of general interest.

Little information is available regarding operations which use colloidal reagents, such as soaps and amines. They should not be impossible as it is well known that soluble salts can be floated with amines in saturated solutions There are, on the other hand, patents regarding flotation of cryolite in sea-water using fatty acids or soaps (6). One of the difficulties, of such operations, however, is that sodium silicate, which is regularly used in this type of flotation, precipitates in sea-water and to a large extent loses its efficiency. Slimes should be neutralized with an organic colloid.

In summary, it is believed that sea-water flotation could be used extensively, but its application is not known in all details because the number of mines where the problem arises is small.

Control of Frothing Power and Selectivity

As mentioned above, sea-water has frothing power, and the use of frothing agents is usually unnecessary. Certain authors even state that some frothing agents develop anti-frothing properties in sea-water.

This question is complex and not well elucidated. It has been noted, in a synthetic sea-water, that certain frothing agents increased the volume of the froth and others decreased it. The order of decreasing frothing power was :

Dowfroth Aerofloat 31 Methylisobutylcarbinol	increase froth volume
Pine oil Cresylic acid Kerosene	practically without effect
Flotol	decreases froth volume

The froth produced in sea-water easily carries gangue slimes. Special precautions are necessary to obtain clean and selective froths, and much attention must be paid to cleaning operations.

The reagent which is often the most important for control of froth is lime. This reagent which is standard for the treatment of copper ores is little used on lead and zinc ores, except when it is necessary to depress pyrite. In sea-water it is nearly always necessary.

It depresses gangue and it gives cleaner froths, but, chiefly, it controls the volume of the froth. With a deficit of lime, the froth is bulky and poorly mineralized. With an excess of lime, on the contrary, the froth is too heavily loaded and of insufficient volume. It overflows with difficulty from the cells. This effect is not apparent on sea-water alone, so that lime appears to act by increasing the mineralization with galena. It is the weight of galena which decreases the volume of the froth. Lime also depresses pyrite and enhances the depressing effect of cyanide on sphalerite and pyrite.

Of course, lime increases the pH but only slightly because sea-water acts as a strong buffer. Natural pH of sea-water is 8.2 On the Carthagene ore an addition of lime of 1 kilogramme per ton, which is normal, gives a pH of 8.7, whereas the same addition made in fresh water would give a pH of 10 or 11.

Cyanide, used in small amount as a depressant, also has an influence on the froth, and, like lime, it gives a cleaner and less abundant froth.

Gieser (4) indicates the use of sodium carbonate and mentions that kerosene gives a more brittle and more selective froth which entrains less pyrite. He advocates the use of kerosene in the cleaning steps. Kerosene is a well-known anti-froth reagent so that this is not surprising.

Differential Flotation

Differential flotation functions in a similar manner using either sea or fresh water. The various reagents, collectors, depressants, and activators retain their normal properties. The same is not true of frothing agents, as stated above.

However, in lead-zinc ores a certain tendency in activation of sphalerite or a certain difficulty in sphalerite depression is sometimes noticed. When

this is the case, and if fresh water is available, it is possible to make a bulk float of galena and sphalerite and to separate the sulphides in a cleaning operation. It is also possible, if the concentrates are contamined by sea-water, to purify them by cleaning in fresh water.

These difficulties are, however, not universal and, frequently, differential flotation is quite normal.

Reagent consumption is, however, usually higher than in soft water. In laboratory tests on ores and dump material from the Carthagene area, cyanide and copper sulphate consumptions were increased by 50 percent in sea-water.

It must be noted, regarding laboratory tests, that these can be effected in synthetic sea-water, such as is used in corrosion laboratories under the condition of properly adjusting the pH. The results are identical. The United States Navy uses a very simple formula for synthetic sea-water (7).

Flotation rate can be affected by sea-water and must be checked when a flotation investigation is made. It has been noticed by Peñarroya that flotation of galena was slow in the absence of lime and that one of the functions of this reagent was to increase the flotation rate. Marmatite or ferruginous sphalerite flotation is accelerated in sea-water. We lack experience regarding non-ferruginous sphalerite.

Metallurgical Results

It is not possible to give comparative industrial results of flotation in sea and in fresh water, as in general the mills have only one type of water available.

Laboratory and pilot-plant tests were made in 1952 and 1953 by the Peñarroya company on ores from Carthagene and, usually, the results were very similar.

We can cite the following results obtained on a low-grade galena sphalerite ore (known as Carthagene silicates) :

		Soft water	Sea water
Feed	Pb (%)	2.20	2.10
"	Zn (%)	0.87	0.82
Cleaned lead concentrate	Pb (%)	56.78	59.40
" " "	Zn (%)	2.32	1.92
Cleaned zinc concentrate	Pb (%)	1.10	3.25
" " "	Zn (%)	41.60	40.51
Tailing	Pb (%)	0.37	0.36
"	Zn (%)	0.40	0.32

The ore is partially oxidized, a fact which explains the relatively high grade of the tailing.

It will be noted that the zinc concentrate is low-grade. This is due to an insufficient liberation of the values and to insufficient cleaning. Another reason is that zinc is in the form of marmatite, a high-iron zinc sulphide.

The commercial mill (Roberto mill) has been in operation since 1957 and uses sea-water exclusively. The tonnage treated is 3,000 metric tons per day. Since 1960, the regrinding and retreatment of lead-zinc concentrates to purify them has been worked out, and a high selectivity is now obtained in spite of the use of sea-water.

The results of August 1965, for example, were as follows :

	Pb (%)	Zn (%)
Feed	1.46	0.56
Lead concentrate	77.70	1.72
Zinc concentrate	0.31	53.13
Tailing	0.15	0.17

The ore is very low-grade but is cheaply mined in an open pit. The marmatite, or ferruginous sphalerite, cannot be raised to a higher grade.

Intermediate Formulas : Sea-water - Fresh Water

We have noted that in certain cases it was of interest to clean in soft water concentrates obtained in sea-water. The froth which overflows from flotation cells has a high pulp density so that it must be diluted for cleaning. Fresh or brackish water is used for dilution and washing through the launders instead of sea-water. This water is largely recycled to the head of the circuit with cleaner tails, and dilutes the original sea-water to a useful effect. In certain cases, one can use in this way 30 percent of fresh water and 70 percent of sea-water.

Another interesting scheme is to feed the mill with water from filtering wells dug on the beach. The filtering action of the sand clears the water. On the other hand, it is often much less loaded with salt than sea-water, this is because, in addition to the sea-water obtained by infiltration, the wells often drain soft water which flows towards the sea from underground water-levels. The composition of the water, however, is variable.

This method was used between 1952 and 1963 at the Argentiera mine in the North of Sardinia and is used at the Laurium mine in Greece.

Chlorine Content of Concentrates

The chlorine content of concentrates should preferably be under 0.05 percent : 0.10 percent (1000 grammes per ton) is often the maximum for the smelter. Filtered concentrates contain about 10 per cent water, and since the chlorine content of sea-water is 19 grammes per litre (21.6 grammes per litre in the Mediterranean), the chlorine content of concentrates amounts to 1,900 grammes per ton, that is, two or three times too high.

Sometimes fresh water is used as wash water on the filter. Filter cakes could also be repulped with fresh water and filtered a second time, but this is usually not necessary.

Mill Construction

Mills using sea-water are situated on the coast-line, and humidity is much higher than in mills which are located at higher elevations.

Moreover, ore pulps made up with sea-water are very corrosive. Chemical corrosion is added to the usual abrasion. It is therefore necessary to use materials resistant to these two types of attack.

Wood, which was formerly widely used (flotation cells, launders, etc.), has now been replaced by plastics and rubber. In the mills of Société de Peñarroya, vinylic plastics are used on a large scale as linings and pipes. In spite of their low hardness, these plastics, being smooth, resist abrasion well, as long as the flow is laminar. But, when the flow is turbulent, it is necessary to use rubber (pipe-bends, moving parts of pumps or flotation machines, etc.). Plastics can also be used to protect concrete. If their costs can be lowered, fluorine compounds and silicones will very likely be of interest.

Alloy steels can, of course, be used but with precaution. Many have only a mediocre resistance in marine environment. When steel is used, it must be painted and the paint must be frequently renewed.

In summary, the most important points to consider are as follows :

Power

Electric motors must be of a type specially constructed for marine service. In some of our mills, infrared heating has been adapted to old motors. Without this precaution, after a fifteen-minute interruption, they cannot be started again. Electric lines must also be protected by plastic tubing.

Piping

Water piping is exclusively in polyvinyl plastics. For ore pulp, the straight portions are in polyvinyl and the bends in reinforced rubber.

These should be in non-putrescible wood or better, in rubber-lined sheet-metal. The agitators should be rubber-lined.

Pumps

Rubber-lined.

Launders

These should be protected by rubber or better, plastic linings.

It should be noted that rubber linings are of interest for use in grinding mills but they are not indispensable.

that the Ni-Cu sulphide ore (-10 mesh) used in the grinding tests was in a partly oxidized state. The dissolved sulphate content of the ore slurry increased with grinding time.

The increase in sulphate content was rapid during the first minute of grinding and it increased gradually over the remainder of the grinding time. The rapid increase in sulphate during the first minute of grinding was concomitant with a rapid decrease in pH. A gradual increase in pH occurred after the first minute of grinding.

The initial rapid increase of sulphate and decrease of pH may be assumed as due to the dissolution of partially oxidized sulphur compounds contained in the ore.

Because of the presence of partially oxidized sulphides and the tendency of these compounds to dissolve in the aqueous slurries, the ball wear vs. grinding time curves were more complex than those found during the iron ore grinding tests.

The use of pH control and corrosion inhibitors reduced corrosive wear of steel balls during the wet grinding of sulphide ore. The pH was controlled by adding NaOH to the slurries. Ball wear decreased above pH 11 until at pH 13.7 there was a 50% reduction in wear.

With 1% $NaNO_2$ in the slurry, a 50% reduction in ball wear was observed at pH 10 whereas a similar reduction in ball wear occurred at pH 13.7 in slurries without $NaNO_2$. Sodium nitrite did not inhibit corrosive wear of grinding balls at initial pH values lower than pH9.

Addition of NaOH and $NaNO_2$ to the ore slurries did not have a significant effect on the work done on the ore during the 20-minute grinding tests as determined by wet-sieve analysis of the ore at the end of each run (%-200 mesh).

Conclusions

- Abrasive wear of carbon-steel grinding balls is accompanied by a significant amount of corrosive wear when certain iron ores and sulphide ores are ground in laboratory ball mills.
- Corrosive wear is reduced by the use of corrosion inhibitors and pH control without affecting the work done on the ore during grinding.
- Addition of sodium borate and sodium nitrite to the ball mill reduced ball wear in iron oxide and sulphide ore slurries by 50%. Sodium silicate reduces ball wear in iron ore slurries by 37%.
- Addition of sodium hydroxide to the ball mill reduces ball wear in sulphide ore slurries. At pH 14.7 wear is reduced by 50%.
- Corrosive wear occurs, in part, by the following overall reaction

$$2Fe + O_2 + 2H_2O \rightarrow 2Fe_2 + 4OH^-$$ □

TABLE 2 – CORRELATION OF CORROSIVE WEAR WITH OXYGEN CONSUMPTION IN IRON ORE SLURRIES

Sea water flotation

L.D. HAIG – SMILLIE

Texada Mines, located at tide water on the west side of Texada Island 100 miles northwest of Vancouver, B.C., runs a mill that operates five days a week producing 1900 long tons of premium sinter iron concentrate per day, assaying 65% iron, 0.055% copper, 0.40% sulphur, and 42% -100 mesh. This is made by blending two iron concentrates:

- A coarse iron concentrate made from ball mill circulating load assaying 64.5% iron, 0.09% copper, 0.50% sulphur, 16% -100 mesh.
- A fine iron concentrate made from rougher flotation tailing, 66% iron, 0.03% copper, 0.25% sulphur, 70% -100 mesh. The proportions depend on the ore being treated. To yield the highest net cash return it is necessary to produce the maximum amount of coarse iron that can be blended with the fine iron concentrates.

Over grinding is costly and undesirable. The primary grind is kept as coarse as possible. Tailing is collected, dewatered, reground and floated for additional copoper recovery.

A by-product copper concentrate, containing gold and silver, high in pyrite, makes the operation economic.

To meet contract specifications processing is done in three distinct circuits, identifiable on Fig. 1.

Coarse Iron Concentrate

A portion of the cyclone underflow in each primary ball mill is cut out and sent to six stage magnetic separation. The concentrate is dewatered in a vibrating dewaterizer and the concentrates go to the drying kiln collecting conveyor.

Fine Iron Concentrate

Primary cyclone overflow goes to a conditioner then to an 8 cell DR=30 followed by an 8 cell =48 Agitair flotation machine. The tailings go to 4 stage magnetic separation. Magnetic concentrate goes to a thickener which also acts as a hydro separator. The underflow is filtered and is conveyed to the 9 ft x 60 ft drying kiln where the moisture is reduced from 10.5 to 5%. The concentrate is weighed and stacked in an open stock pile.

Regrinding and Flotation

All the iron circuit tailings are collected, dewatered and ground in two parallel regrind circuits.

The coarse iron tailing is divided between two 36 in. classifiers. Sands from the first classifier go to an 8 ft x 10 ft Allis-Chalmers ball mill then an 8 cell =48 Agitair flotation machine, followed by single stage magnetic separation. Separator tailing goes to the fine iron tailing sump.

First coppper cleaner tailings are retreated in this circuit.

Sands from the second classifier go to an 8 ft x 12 ft Marcy regrind ball mill, then to an 8 cell =48 Agitair machine. Tailings go to a double drum magnetic separator and then to waste. The fine iron tailings are cyclomed to remove the sands for regrinding in the 8 ft x 12 ft Marcy mill.

The magnetic separator tailing is very dilute. Cycloning then is essentially a dewatering operation. This overflow water plus excess classifier weir overflow and the recleaner tailing is floated in a 6 cell DR#30 flotation machine. Tailings from the DR go to a double drum separator then to waste.

Flotation History

Fresh and reclaimed water supplies were not adequate. In order to maintain the operation it was necessary to supplement the water supply with sea water.

It was recognized from the start that Texada ore pulps were subject to a buffering action. Lime additions from two to five pounds per ton were required to change the alkalinity from the normal pH8. Increasing the lime increased the grade of concentrate but very substantially reduced the recovery.

Microscopic examination revealed a slime and a carbonate coating on the sulphide mineral. Frequently numerous clean chalcopyrite grains could be found in the tailing.

In 1966 tailings disposal problems made it necessary to add an additional 500 g.p.m. of sea water to the tail race. Copper froth began to appear on the lower reaches of the tailings launder.

Some of the problems in the flotation circuit were:

- Lime, being a flocculand, was favoring slime coatings on the mineral surface.
- The calcium ion and or the OH ion was excluding or displacing the xanthate from absorbing onto the mineral surface.
- The calcium coating deposited could be dissolved with excess dilution.
- Sea water had no detrimental effect on flotation.

All the lime was removed from the circuit and just enough soda ash added to ensure an active pyrite float. Recoveries increased enormously.

In 1966 the mine went to trackless mining and underground water supplies were unusable due to colloidal slimes and oil. The unusually dry season created a critical water shortage so the mill went to 100% sea water.

Solubility

The 8 ft x 12 ft regrind ball mill was designed to operate in sea water. Plant scale tests were run to determine the solubility of Texada copper in sea water. The maximum copper detected was 0.25 ppm – the average 0.004 ppm. Copper values while milling in fresh water were so similar that the operators concluded that there was no appreciable solution of copper during processing. This is not true for several mines in B.C. Corrosion is severe because there is no stifling by corrosion products. But it is less severe in sea water than in fresh or fresh-sea mixtures.

REAGENT CONSUMPTION PER LONG TON ON A YEARLY BASIS FOR THREE TYPICAL PERIODS

Reagent	1973	1967	1965
Sodium Isopropyl Xanthate	0.024	0.115	0.058
Reagent 238	0.010	0.007	0.013
Reagent 242	0.001	0.001	
Aerofloat 33	0.005	0.0016	0.001
Aerofroth 65	0.016	0.023	0.025
Z-200	0.005	0.004	–
Soda Ash	0.048	–	–
Sodium Cyanide	0.002	0.0002	0.0002
Lime	0.066	0.45	0.71

Reagent consumption has been reduced in full use of sea water.

Corrosion grinding media

A sharp increase in the grinding media and liner steel consumption was anticipated with sea water in contact with fresh abraded iron and steel.

Steel consumption did not increase until the fall of 1970 when a fourth ball mill was started. Consumption rose from 0.626 to 0.787 pounds per long ton – entirely due to finer grinding.

No sea water entered the grinding circuit until 1960. During the first years of operation grate and pan liner wear was excessive. It was obvious from the worn parts that electrolytic corrosion and not abrasion was the cause of the failure. The nickel content of the liners was increased and 3/8 in. stainless steel shims were placed under the grates. The problem disappeared. Liner steel consumption is down in primary grinding with the full use of sea water.

Regrind ball mill

Corrosion is most severe with large amounts of pyrite in aerated sea water. Mixtures of sea and fresh water are the most corrosive of all.

The regrind mill was designed to be operated in sea water, grinding the highly pyritic tailing and the platey cupriferous pyrite from the rougher concentrate.

Two sets of half worn Manganese feed end liners lasted 11 months each. Two sets of new Ni-Hard discharge liners lasted 10 months each. Manganese lifters and chrome molly shell plates gave normal life. Liner bolts required very heavy maintenance as they dissolved very rapidly. The mill was converted to rubber in 1966 using standard profile Skega. Shell Plates are still in place.

Regrind mill

The regrind mill was installed with a half worn set of Ni-Hard liners. These liners lasted 20 months and were changed only because it was not practical to change single worn liners. The service life was far in excess of what was anticipated. The mill was rubber lined.

Corrosion – filters

With the use of sea water corrosion problems were greatly reduced. Boot parts originally lasting 1-1/3 yrs. now last over seven years. Valve life is more than doubled.

Marine life

Marine life is always a problem when using sea water. The foot valves, intake, delivery lines, and the holding tanks rapidly build up with barnacles, mussels, oysters, clams, starfish, sea urchins, and sea worms up to 18 in. long and 1/2 in. or more in thickness.

This marine life can easily be destroyed but most of it remains fastened to the place of growth for long periods of time making an excellent site for new growth. When these shell fish do come loose they drift into pipe lines and cut off the flow of water. They are particularly troublesome in magnetic separator spiggots.

Several quick hard air blows are made into the water filled pipe then the bottom drain is quickly opened. If there is any plug up, the process is repeated. Shell removal is excellent and complete.

Summing up the 17 years of operation, it was found that the full use of sea water gives a very stable, easily controlled float. Reagent consumption is greatly reduced and reagent feeding has been simplified. The natural pH of the sea water is the most satisfactory level for Texada ores. It is extremely important to float certain types of pyrite and this is best done at low pH after making allowance for final grinding. Steel and liner consumption is less in full sea water than it was in fresh and mixtures of sea and fresh water.

Atmospheric corrosion is severe and causes more problems than the sea water in the processing. This is a location problem and not a function of the use of sea water. □

FLOTATION OF PYRITE AND GOLD

Gold and silver often occur in "refractory" sulfide ores, and they can sometimes best be recovered by flotation to a concentrate for roasting and leaching or for shipment to a smelter. The flotation tailings may also contain enough cyanide-soluble gold to justify leaching. Alternatively, gold and pyrite can be floated in order to make a smaller, more concentrated tonnage of material which can be subjected to very much more aggressive fine-grinding and concentrated cyanide leaching, while the flotation tailings receive a standard leaching treatment.

When a flotation concentrator is located near a cyanide leach plant, great care must be exercised if water is to be reclaimed for reuse in the mill from the tailings pond. It has been common practice, especially in Canada and Australia, to recombine the leached calcine tailings with the flotation tailings and to dispose of them to the same tailings pond as described in the trip report on GIANT YELLOWKNIFE MINES. In the case of GIANT, no water is recycled. Decant water is treated by alkaline chlorination and discharged to the lake via a creek. If such tailings water is to be recycled to the flotation mill, a very real danger exists that there could be a deterioration in flotation recovery as cyanide is an effective depressant of pyrite.

Where tailings are backfilled to underground mines, it is possible that minewater may find a measurable cyanide level as has been the case at Homestake Mining Company, Lead, South Dakota. Although the Lead minewater is not used in a flotation circuit, it serves as an example of how cyanide can get into water. Another example of minewater that contained a low cyanide level is the GIANT mine referred to above and described in Appendix I. In the case of Giant, backfill is not practised, but cyanide reached the underground minewater through seepage from their final decanting pond until the new cyanide treatment plant was installed upstream of it.

What this leads to is that when gold-pyrite concentrates are to be recovered by flotation in the vicinity of a cyanide-leach plant, very careful consideration must be given to how water from the two circuits will be kept isolated to avoid getting cyanide into the flotation circuit, or how it is to be treated to remove cyanide to levels that will not cause a problem.

GOLD-PYRITE FLOTATION-WITWATERSRAND

Hartebeestfontein Gold Mining Company Limited

At 'HARTIES,' a pyrite gold-uranium concentrate is floated at a high pH from run of mine ore. After ultra-fine grinding, the concentrate is leached first in sulfuric acid to recover uranium and then in cyanide to leach gold. The flotation tailings are also leached for uranium and gold recovery in that sequence. The reason for floating a concentrate is that the smaller volume of high grade concentrate (250 g/t gold) allows more aggressive treatment at an affordable cost VIZ fine-grinding (99% minus 44 u), and leaching at higher reagent concentrations (0.8% NaCN) and for longer times than would be economically advantageous for bulk ore. The 'HARTIES' flowsheet achieves a higher overall recovery than other Witwatersrand mills.

'HARTIES' was described in RANDOL (1983). The cyanided pyrite concentrate is roasted to produce sulfuric acid which is used to leach uranium and in that way, no cyanide in the leached concentrate gets into the water system. After leaching the flotation tailings, these are disposed of to a tailings pond and, undoubtably, decant solutions are recycled. It is not known how cyanide in the recycled solution is prevented from returning to the flotation plants. One possibility is that residence time in the tailings pond and reclaimed water reservoir is long enough for cyanide to be lost by natural degradation. Alternatively, water used in the flotation plants may be recovered for reuse in the primary milling and flotation circuit by solid liquid separation not shown on the general arrangement flowsheet below.

Final cyanide-leached tails are filtered to recover a pregnant solution. Soluble gold is recovered by washing with only 0.5% soluble loss on one state of filtration which indicates that very little cyanide is left in the filter cake when the tailings are repulped. By

repulping with tailings return solution rather than barrens which contain cyanide, cyanide levels are kept very low in the tailings pond solution to start with. Cyanide in slimes dam runoff water from Loraine is shown in one of the documents inserted below to be unsuitable for use in flotation plants, even if it contains only 1 ppm cyanide. The effect of cyanide on high pH pyrite flotation is discussed below.

ERGO

The East Rand Gold and Uranium Recovery Ltd. (ERGO) operation recovers a gold-pyrite-uranium concentrate by flotation from 1.5 million tons per month of reclaimed tailings.

Water management at this operation is described in Appendix I. In this case, flotation is operated at an acid pH. Water used in the process is made up of underground minewater and reclaimed tailings solution. There are two main challenges:

1) Scaling due to high concentrations of gypsum.

2) Ultimately TDS of effluents discharged may have to be reduced to meet new effluent regulations.

In 1985, ERGO started up a massive new leach and CIP gold recovery operation to recover gold that otherwise would not have been recovered in the flotation step. Here it is interesting to see how cyanide in the CIL tails effluent is kept separate from the flotation plant solution. Cyanide in the calcine leach tailings is reduced to below 0.5 ppm by treatment with lime and uranium plant raffinate containing a very high iron content. In the new CIL plant, the last 7 of 11 stages of carbon contactors were installed to remove cyanide from the pulp solution prior to being pumped to a huge new tailings dam from which water is recovered for reuse. Tailings from the SIMMERGO CIP plant also go to this tailings dam. The recovered decanted water is used in part in the flotation circuit as can be seen in their water balance diagram shown below.

Rand Mines Milling and Mining Co. Ltd. - RM3

This operation, known as RM3, on the Witwatersrand also combines flotation of a pyrite-gold-uranium concentrate with cyanidation and CIP gold recovery and recycles large volumes of water as shown in the flowsheet overleaf..

In this case, water quality has presented some problems, although not in the flotation circuit, even though quite large volumes of CIP tailings decant water are returned to the sand dump repulper ahead of clarification and flotation. Either the residual cyanide is lost by natural degradation, or it is taken out of solution by large amounts of iron in the recycled solution and, most likely, any residual cyanide is lost when the tailings are repulped at pH 2.5 which would volatilize any cyanide.

RM3 uses as much recycled water as possible as well as surface water from a local stream. Some initial metallurgical recovery problems were attributed to the quality of this streamwater which was affected by upstream industry and was thought to be one possible cause of carbon fouling in the CIP circuit.

Buffelsfontein Gold Mining Co. Ltd.

'BUFFELS' has applied an interesting wrinkle to gold-pyrite flotation from current gold leach tails. In this case, after leaching gold, the tailings are acidified to pH 3.5 and powdered activated carbon added to the pulp. In the ensuing flotation step, this gains two advantages:

1) The activated carbon at low pH helps to decompose any cyanide that may be left in the tailings pulp, thereby avoiding the possibility of pyrite being depressed.

2) The powdered carbon adsorbs residual gold which is recovered with the pyrite concentrate and recovered by cyanidation of a calcine after roasting.

More will be learned about the effectiveness of this step at the XVe IMPC Congress in Cannes, France, when VAN ASWEGEN (1985) describes the process and results achieved. Meanwhile, enquiries may be directed to:

RM3 FLOWSHEET

LIME TREATMENT OF FLOTATION PLANT DILUTION WATER

The Anglo American Research Laboratories undertook detailed flotation tests to determine whether or not a tailings thickener should be operated in the alkaline pH range and, if so, at what pH to recover water of optimum quality for recycle to a flotation plant recovering pyrite and gold.

Their results were inconclusive. Using water from one tailings dam and two sets of plant waters, lime treatment of the flotation plant dilution water from pH 7.5 to 9.5 produced no significant improvement in flotation response. However, when a sample from a second dam and another set of plant waters were used for a similar test, there was a dramatic improvement in the pyrite flotation response after lime treatment of the water. This had the effect of allowing significantly more gold to be recovered direct to final product from the rougher flotation circuit compared to when untreated water was used. Generally, however, lime treatment to pH 7.5 produced as good results as to pH 9.

In a second set of tests using the standard OFS mill flotation technique on a sample of tailings from a tailings dam near Welkom, Orange Free State, it was found that if the flotation plant dilution water was treated by adding lime to pH 10.5 and then settled prior to its use for density control measures, then the initial pyrite grade could be increased from 24-25% sulfide sulfur to 30-37% S. This means that of the gold recovered in the rougher flotation circuit, 60% could be routed direct to final product and 40% to the cleaner circuit when treated water is used. When untreated water is used, all the rougher concentrate must be routed to the cleaner circuit. Treatment of the flotation plant dilution water had a less significant effect when the standard flotation method was used.

When another dam sample was tested using fresh plant water samples, only marginal benefits were found from the treating of the water with lime, and no optimum pH could be defined.

Clearly, water chemistry involved here is complex, and more may be learned through further testwork. This topic might be discussed with:

from one to the other and also quantify the degree to which recoveries are reduced by the presence of cyanide in recovered water when used for flotation of gold, uranium, and pyrite.

It is also interesting that some water samples tested gave better recoveries than Rand Water Board water which is the regional water supply usually used.

More information on water quality effects on flotation recovery of gold, pyrite, and uranium can be obtained from the metallurgists that undertook this excellent piece of research:

USE OF RECLAIMED SEWAGE WATER IN FLOTATION

In several parts of the world, water is in short supply, and the mineral processing industry has sought to use reclaimed sewage water in flotation recovery operations. This has often led to poor results, and the industry has sought to find out why and a treatment method which would make the water amenable to mineral processing, especially flotation.

In talking to industry, one does come across cases where reclaimed or even raw sewage is added to tailings ponds and where water containing various amounts of blended wastewater of this kind is used in mineral processing. There are many more people involved with mineral processing, it seems, who say that it cannot and should not be done.

Above, the example of CLIMAX MOLYBDENUM DIV. was mentioned where sewage from a mining camp, when it was formerly located at Climax, was discharged to their tailings pond, and the negative effects on flotation were counteracted by adding activated carbon to the pulp. In that case, the purpose of disposing of sewage to the tailings pond was to avoid the need for a sewage treatment plant. In any case, the volume of wastewate added to the system in this way would have been miniscual in relation to the volume of tailings and the volume of water recycled to the plant. CLIMAX testwork dated 1963 by Ralph Meyertons showed that even traces of stearic acid is detrimental to molybdenite recovery. Stearates are constituents of soaps that can occur in sewage effluents which

provides a lead to one possible cause of flotation problems when sewage reclaim water is used in Cu-Mo mills.

The following is an excerpt from an ANGLOVAAL report describing testwork aimed at exploring the use of alternate sources of water.

2. INTRODUCTION

Current drought conditions have restricted the off-take of potable water for metallurgical purposes.

The aim of this investigation is to evaluate the various unused Loraine local waters for possible future use in the flotation application, by a series of comparative flotation tests.

2.1 Inference

2.1.1 Slimes dam run-off water

2.1.1.1 The presence of trace quantities of residual cyanide make this water unsuitable for use in the flotation plant.

Tests revealed that cyanide concentrations as low as 1 ppm have a detrimental effect on flotation performance.

Table 1 Cyanide Concentrations versus Gold, Sulphur and Uranium Rougher Recoveries

Cyanide level	Actual Recovery % (t = 12 min)		
ppm NaCN	Gold	Uranium	Sulphur
8,5 ppm	75,05	10,37	16,99
6,2 ppm	77,52	15,72	36,39
3,5 ppm	80,53	14,78	41,02
2,5 ppm	82,13	21,55	62,18
1,3 ppm	77,40	19,85	68,16
Nil	79,20	25,35	86,12

2.1.1.2 At the extremely high cyanide levels (180 ppm), encountered when using undiluted slimes run-off water, even gold, which appears less sensitive to cyanide depression, was completely depressed and only 3,0% could be recovered by flotation.

2.1.2 Swartpan water

Treating the Swartpan water by increasing the pH to >11,0 and removing the precipitated solids prior to use, increased the recoveries of gold, uranium and sulphur to levels higher than the standard water.

Table 2 Swartpan Water - Gold, Uranium and Sulphur Recoveries

Water	Actual Recovery - % (t = 12 min)		
	Gold	Uranium	Sulphur
Swartpan (Untreated)	69,57	14,56	92,20
Swartpan (Treated)	87,20	32,83	92,30
Rand Water	82,95	27,17	86,50

2.1.3 Mill return water

As expected, excellent recoveries of gold, uranium and sulphur were obtained with this water.

Table 3 Mill Return Water - Gold, Uranium and Sulphur Recoveries

Water	Actual Recovery - % (t = 12 min)		
	Gold	Uranium	Sulphur
Mill return water	89,13	36,95	95,60
Rand Water	82,95	27,17	86,50

Residual flotation reagents in the mill return water enhanced the collectors added during the test to produce these excellent results.

2.1.4 Stinkpan water

2.1.4.1 Stinkpan water, both aged and fresh, had a very detrimental effect on gold, uranium and sulphur recovery.

2.1.4.2 Even at the 10% replacement level, gold recoveries were considerably lower than the Rand Water standard (see Table 4).

Sulphur and uranium recoveries appear to be little affected at this replacement level.

Table 4 Stinkpan Water - Gold, Uranium and Sulphur Recoveries

Water and % Replacement	Actual Recovery - % (t = 12 min)		
	Gold	Uranium	Sulphur
Aged			
100 %	13,59	7,65	22,02
50 %	39,47	15,24	49,29
10 %	71,40	27,04	90,35
Fresh			
100 %	52,99	27,81	85,22
50 %	67,16	30,16	91,16
10 %	74,72	29,89	91,11
Rand Water	82,95	27,27	86,50

2.1.5 Sewage water

The flotation behaviour of sewage water appeared very similar to aged Stinkpan water, recoveries of gold, uranium and sulphur decreasing as the water replacement percentage increased (see Table 5).

Table 5 Loraine Sewage Water - Gold, Uranium and Sulphur Recoveries

Water and % Replacement	Actual Recovery - % (t = 12 min)		
	Gold	Uranium	Sulphur
Sewage Water			
100 %	13,58	6,35	15,83
50 %	46,17	14,59	69,23
10 %	76,52	27,80	92,46
Rand Water	82,95	27,17	86,50

3. RECOMMENDATIONS

3.1 Slimes dam run-off water, Stinkpan water and sewage water should not be used in the flotation plant in their present untreated form, as their use will result in lower gold, uranium and sulphur recoveries.

3.1.1 Further testwork sould be conducted on the slimes dam run-off water to investigage free and complex cyanide removal by such methods as activated carbon, ion exchange or sulphur dioxide treatment to render this water suitable for flotation usage.

3.1.2 Sewage effluent from the new sewage treatment plant to be erected at Loraine should be evaluated when this water becomes available, especially if the plant has been designed to remove phosphates from the sewage effluent. Water quality would then be similar to the Stilfontein new plant sewage water, which was suitable for flotation.

3.2 Test work should be conducted to optimise flotation circuits to make them less sensitive to waters of poorer quality.

Areas which could be investigated include flotation reagents suites, pH and conditioning time.

3.3 The development of other metallurgical routes which would be more water efficient and less sensitive to water quality.

3.4 Although no flotation evaluation was conducted on the sample of underground (dated 12 May 1983) submitted for analysis, analytical results indicate that it is highly unlikely to be harmful when used for flotation purposes.

FALCONBRIDGE, at both their Falconbridge and Onaping, Ontario operations, disposes of sewage into their tailings and minewater system but again, the volumes are miniscual in relation to the tailings, and no adverse effects on flotation results have been found nor would be expected.

The type of sewage water use of interest here is where it is added as a supplementary water supply and constitutes a significant percentage of the water used in the plant. To date, no operation was found which relies heavily on reclaimed sewage water as a source of process water. It was rumored (unconfirmed) that Chuqinquamata, Division of CODELCO, reuses their treated sewage water in the mill.

FISHER and RUDY (1976) described an investigation into sewage wastewater use in copper-molybdenum recovery operations. Their paper was inserted above. They showed a distinctly improved copper and, particularly, molybdenum recovery when demineralized water is used compared with sewage effluent. They showed how recovery differences were greater near neutral pH than at high pH values and that when the wastewater is treated with activated carbon, recoveries improve but not to the levels achieved with demineralized water. Sewage water caused a reduction in recovery of 2.4% and 16.2% for copper and molybdenum respectively. There were other effects such as uncontrolable frothing.

They found that tertiary treatment of sewage effluent by activated carbon results in a significant improvement in terms of flotation recoveries. Ion exchange removal of anions from sewage effluent results in a significant improvement in copper and Mo recovery and also reduced the foaming effects. They concluded that it was the anion content that is mainly responsible for deterioration in the moly and copper recovery.

Foam fractionation improved the frothing problem but not the metal recovery deterioration.

In flotation of pyrite and gold from Witwatersrand tailings, the persistant drought of 1982-1984 created an urgent need to conserve water, and mining houses explored the possibility of using reclaimed sewage water in their operations. A few observations and opinions are of interest:

- <u>President Brand Gold Mining Co. Ltd., Welkom, O.F.S.</u>
  There are several large mines and mills around the city of Welkom, Orange Free State. These include gold cyanidation mills and uranium leaching plants, flotation plants, and roasting operations followed by calcine leaching to recover gold. The large municipal area as well as the huge mineworker hostels accommodating tens of thousands of people generate large volumes of sewage water. Cases have occurred where treated sewage effluent got mixed in with tailings reclaim water used in the flotation plants. It was found that when sewage water gets into the pulp, then sporadically the recovery of gold and pyrite are adversely affected. This operator

observation was not supported by hard data since there are so many contributing factors to flotation plant performance that none could say for certain what caused the sporadic reductions in flotation efficiency.

- When various individuals involved were questioned about the reduced recovery of gold/pyrite in flotation plants when sewage water is mixed into the system, several speculations as to the cause surfaced:

  -- Polyacrylate coagulants/flocculants used in the sewage plant may interfere with flotation.

  -- Organic compounds in sewage similar to humic acids interfere with flotation.

  -- Residual detergents and soaps interfere with flotation.

  None of these was backed up by data. The problem of analyzing for low levels of organic polymer surfactants in sewage water was mentioned.

- A consulting metallurgist at a mining house head office in Johannesburg pointed out that it had been found that when reclaimed sewage effluent is used in the Peabody scrubbers, that clean pyrite roaster gas (prior to conversion of SO_2 to SO_3), then the resulting water can be used in flotation circuits without reduced flotation recoveries. Again, no hard data was presented to support this claim.

- The Anglo American Research Laboratories undertook several intensive flotation tests on a large laboratory scale both with and without sewage plant effluent addition. These tests were inconclusive.

Anglovaal Research Laboratory Tests

Anglovaal Research Laboratories tested treated sewage water from two adjacent sewage plants located at Stilfontein Municipality in the Transvaal at their laboratories to determine relative performance in flotation of pyrite and gold. Their tests were for high pH flotation similar to that employed at Hartebeestfontein Gold Mining Company (HARTIES). The purpose of their tests was to determine whether Stilfontein sewage water could be used as an alternate water supply in the Hartebeestfontein two-shaft flotation plant.

The two sewage treatment plants sampled include an 'old plant' which uses a standard trickle filter for secondary treatment. The 'new plant' employs activated sludge technology for reduction of ammonia and phosphate.

The Anglovaal Research Labs' results are summarized as below. Additional discussion on this extremely useful quantitative research could be directed to:

ANGLOVAAL RESEARCH LABORATORIES

These are some aspects of how the tests were performed that Anglovaal asked to be kept confidential.

2. INTRODUCTION

The water optimisation programme has revealed that Stilfontein sewage effluent may be a valuable additional source of water for metallurgical purposes at Hartebeestfontein.

This test work investigates only its effect on gold, sulphur and uranium recovery by flotation.

2.1 Inference

2.1.1 Summary

2.1.1.1 Stilfontein 'Old Plant' sewage water

Wide variations in flotation behaviour were obtained using Stilfontein old plant water. These ranged from totally unacceptable results to results which were better than the standard Rand water tests.

Flotation behaviour appears to be linked to the quality of this effluent water. When high phosphate levels occur together with very low Redox potentials, poor flotation conditions result, producing high mass low grade concentrate from stable voluminuous froths.

When the Redox potential of the water is higher, even though phosphates are present, acceptable metallurgy is obtained (as in water sample received 2 May 1983).

Table 1 Stilfontein Old Plant Water

Poor Flotation (25. 4.83)			Good Flotation (2. 5.83)		
pH	EH *	P ppm	pH	EH *	P ppm
7,76	-256	13,5	7,34	125	10.4

* millivolts versus standard calomel electrode

2.1.1.2 Stilfontein 'New Plant' sewage water

Stilfontein new plant sewage water produced very similar results to the standard Rand water. Froth texture and stability were of such a nature as not to produce problems on the concentrator, and, if this water was phased in progressively over a period of time, no flotation problem should be encountered.

Table 2 Stilfontein New Plant Water

Good Flotation (25. 4.83)			Good Flotation (2. 5.83)		
pH	EH *	P ppm	pH	EH *	P ppm
7,73	- 25	5,7	7,65	134	2,7

* millivolts - versus standard calomel electrode

Complete chemical analyses of all water types are included in Table 3.

2.1.2 Gold Recovery/Sulphur Grade Curves (Roughers)

Figures I and II appended, compare the flotation behaviour of the various water types and blends with respect to gold recovery versus rougher concentrate sulphur grades.

From the figures, the following conclusions can be drawn :

2.1.2.1 Stilfontein new plant sewage water behaved very similarly to Rand water.

2.1.2.2 Stilfontein old plant sewage water (Rec. 25.4.83) was unsuitable for use in the flotation plant, except at addition levels lower than 10%, however.

2.1.2.3 Old plant water (rec. 2. 5. 83) performed slightly better than the standard water.

2.1.2.4 Figure I clearly shows that longer conditioning, i.e. 20 minutes, improved the flotation behaviour of the sewage water (composite of equal parts old, new and worst case), producing a recovery/grade curve which was higher than the standard Rand water test (unconditioned).

2.1.2.5 When poor quality waters, having excessive frothing properties caused by polyphosphates, are used in flotation, the addition of frother plays an important part in the recovery/grade relationship. As the frother addition is reduced to gold recovery drops and sulphur grade increases at constant flotation time (compare 'worst case' 50% 10 and 14 g/ton frother and 'old plant' 100% 10 and 4 g/ton frother). In effect, the rougher float is cleaner (less gangue floats) but the kinetics are a bit slower.

3. RECOMMENDATIONS

3.1 Old plant sewage water should not be used in Hartebeestfontein 2 Shaft flotation plant because of the wide variations of water quality emanating from this plant.

Poor quality sewage water could have disastrous effects on flotation performance.

3.2 From the samples of Stilfontein new plant water evaluated, it appears that this water type could be used in the Hartebeestfontein 2 Shaft flotation plant.

Progressive introduction of the water over a given time period, together with careful frother control, will ensure the least disruption to the circuit.

4. SAMPLES

4.1 Ore Samples

4.1.1 Hartebeestfontein 2 Shaft Rod Mill Feed (Tests 1 to 21)

Laboratory Reference Number RS 49083

Chemical Analysis

Gold	=	12,665 g/ton
Uranium	=	120,75 g/ton
Sulphur	=	1,258 %

4.1.2 Hartebeestfontein 2 Shaft Rod Mill Feed (Tests 22 to 35)

Laboratory Reference Number RS 47044

Chemical Analysis

Gold	=	12,379 g/ton
Uranium	=	127,90 g/ton
Sulphur	=	1,271 %

4.2 Water Samples

4.2.1 Stilfontein sewage water - new plant (Rec. 25 April 1983)

4.2.2 Stilfontein sewage water - old plant (Rec. 24 May 1983)

4.2.3 Stilfontein sewage water - worst case (Rec. 24 May 1983)

4.2.4 Stilfontein sewage water - new plant (Rec. 2 May 1983)

4.2.5 Stilfontein sewage water - old plant (Rec. 2 May 1983)

5. EXPERIMENTAL

5.1 Preparation of Flotation Feed

Representative 2 000 gm portions of Hartebeestfontein 2 Shaft rod mill feed were milled for various times, in a stainless steel laboratory rod mill to produce a milling curve.

The water under test was then used for milling to produce flotation feeds of 65% - 75 µm.

After milling the pulp was diluted to a relative density of 1,242 prior to flotation.

Test water was used for all washing and dilution purposes.

5.2 Flotation Technique

5.2.1 Flotation conditions are outlined below :

Table 4 Flotation Conditions

Stage	Reagent Addition - g/ton				Time - minutes			pH
	$CuSO_4.5H_2O$	AP 3477	SNPX	S 5004	Grind	Condition	Froth	
Rod mill	-	-	-	-	22	-	-	
Pyrite Ro. 0	80	-	-	-	-	2	-	11,0
1	-	15	40	4-10	-	1	1	
2							1	
4							2	
8				4		-	4	
12							4	

Note: (i) AP 3477 = Aero Promoter 3477
S 5004 = Senfroth 5004

(ii) pH was adjusted to pH 11,0 by lime addition prior to conditioning

5.2.2 All tests were conducted in a Denver D 12 laboratory flotation cell, using the following conditions :

	Cell size litres	Impeller speed	R.D	Solids %
Conditioning and flotation	5,2	1 800	1,242	31

5.2.3 In all tests, five separate rougher concentrate were collected over a 12 minute period and cumulatively represent recoveries at 1, 2, 4, 8 and 12 minutes, respectively.

6. RESULTS

6.1 Stilfontein Sewage Water (Rec. 25 April 1983)

6.1.1 Mineral Separation

Gold recovery/sulphur rougher concentrate grade curves were used to evaluate mineral/gangue separation (Figure I).

Curves in the upper right hand section indicate gold separation - the higher the curve in that direction the better the separation, while curves in the lower left hand quadrant represent poorer separation.

6.1.1.1 Stilfontein Sewage Water - New Plant

Mineral/gangue separation produced by this water type was very similar to the Rand water standard (See Figure I).

The rates of flotation for gold, uranium, sulphur and gangue for the sewage water were higher than the standard water.

Sulphur rougher concentrate grade is governed by the sulphur and gangue kinetics and as the increase in sulphur flotation rate was higher than the increase in gangue flotation rate, no marked change in sulphur rougher concentrate grade occurred.

K values for the various sewage water blends relative to the standard Rand water are presented below in Table 5. Actual rate constants are tabulated in Table 6.

Table 5 *Relative Au, U_3O_8 and S Rate Constants

Percent Test water	Frother g/ton	Relative Rate Constants			
		Gold	Uranium	Sulphur	Gangue
Rand Water					
100 %	14	1,000	1,000	1,000	1,000
Stilfontein 'New Plant' Sewage Water					
10 %	14	1,3785	1,5167	1,6731	1,2414
50 %	14	1,3134	1,5599	2,1699	1,4385
100 %	10	1,4076	1,3568	2,7126	1,4578
Stilfontein 'Old Plant' Sewage Water					
10 %	14	1,5225	2,0001	2,2868	1,9441
100 %	10	0,5002	0,6709	1,0985	4,3298
100 %	4	0,3013	0,2884	0,6656	2,6255
Stilfontein 'Worst Case' Sewage Water					
10 %	14	1,0626	1,1242	1,2129	1,0158
50 %	14	1,6812	2,0865	2,5588	3,6138
50 %	10	1,0485	0,9824	1,3613	1,0229
100 %	10	1,3408	1,1893	1,7518	1,5193

$$* \quad \text{Relative rate constant} = \frac{\text{Test water rate constant}}{\text{Standard water rate constant}}$$

6.1.1.2 Stilfontein Sewage Water - Old Plant

Stilfontein old plant sewage water at the 10% replacement level produced mineral/gangue separations which were just acceptable (See Figure I).

At the 100% replacement level extremely poor mineral/gangue separation occurred. This condition was caused by a voluminuous non-selective uncontrollable froth which persisted despite reduced frother addition (See Figure I).

The rate of flotation of gold, uranium and sulphur dropped drastically, while the gangue flotation rate increased so producing low grade concentrates and poor recoveries.

Relative and actual K values are presented in Tables 5 and 6.

6.1.1.3 Stilfontein Sewage Water - Worst Case

Mineral/gangue separation at the 10% replacement level was the lowest curve in the family of acceptable results (See Figure I). However, as the replacement level rose to the 50% level, a marked drop in mineral separation occurred (See Figure I).

On reducing the frother addition level from 14 to 10 gram/ton for the subsequent 50 and 100% replacement tests, acceptable mineral separations were obtained (See Figure I).

The rate of flotation of gold, uranium, sulphur and gangue were higher than the standard.

Uranium and sulphur recoveries for the sewage blends were generally equal to or better than the Rand water standard.

Table 7 Gold, U_3O_8 and Sulphur Actual Recoveries for Various Sewage Water Blends (Rec. 25.4.83)

6.2 Stilfontein Sewage Water (Received 2 May 1983)

6.2.1 Mineral Separation

Gold recovery/sulphur rougher concentrate grade curves were used to evaluate mineral/gangue separation (See Figure II).

6.2.1.1 Stilfontein Sewage Water - New Plant

Similar mineral/gangue separations to Rand water were obtained at all percentage replacements using this sample of Stilfontein new plant sewage water (See Figure II).

5.3.2 Results clearly show the vast improvement brought about in the flotation behaviour of these waters when conditioned.

Tables 13 to 17 below compare results for the various water types and conditions.

8. SPECIFIC ENVIRONMENTAL PROBLEMS ASSOCIATED WITH THE PROCESSING OF MINERALS

Don H. Baker, Jr.
Director New Mexico Bureau of Mines
and Mineral Resources
New Mexico Institute of Mining and Technology
Socorro, New Mexico

Roshan B. Bhappu
Vice President Mountain States
Research and Development
Tucson, Arizona

ABSTRACT

This paper considers specific environmental problems associated with the processing of minerals. The topics covered include the development of special attributes of mineral processing engineers as pollution experts; a discussion on the environmental problems associated with the use of common and specific flotation reagents; an examination of the effect of hazardous metallic ions in plant effluents; and a plea for the incorporation of environmental awareness and training as integral parts of mineral engineering curricula.

INTRODUCTION

In his persistent efforts to satisfy his insatiable demand for mineral resources, man has often exploited them without regard to consequence. It would be fruitless to deny that the mineral industry by its very nature contributes to certain pollution problems. Open pit mining, underground operations,

hydraulic mining, oil and gas production, metal smelting, fuel refining and all other extractive efforts disturb our environment to some degree. Some damage to the environment is inevitable even with the best extraction procedure and land restoration methods. The mined ores are moved and handled several times before they are processed, thus creating dust, noise, and other forms of air pollution. Mining wastes and drainage usually contribute to stream pollution and create a solid waste disposal problem.

It is for these reasons that the mineral industry is identified by a large segment of the uninformed public as a major contributor to the overall pollution problem. This is far from the truth. In the first place, only a small percentage (about 0.14 per cent) of the total land in the United States has been adversely affected by mining. Moreover, practically no public attention has been drawn to the extensive as well as expensive efforts made by the mineral industry to minimize the environmental impact of its operations. Many extractive companies take great pride in the responsible manner in which they have conducted their business. Their efforts in the environmental control field have gained national recognition and praise from government agencies as well as the public.

As members of a progressive engineering society it is our responsibility to achieve maximum conservation of a finite supply of minerals with minimum contamination of the environment. We must continue to develop and implement operational practices, processes and techniques to achieve the above goal and to assure full consideration of health, safety and welfare of the public as well as the people working in our industry.

As mineral processing engineers we must do our part in creating a safe and pollution-free environment in and around our mills and processing plants. Moreover, because of our special expertise in understanding pollution situations and in prescribing economic solutions to such problems, it is imperative that we provide the needed lead not only in our own industry but also in other fields of endeavor.

It is not the intention of the authors to cover in detail the environmental problems associated with mineral processing.[1-4] Rather, the primary objectives are to develop the special attributes of mineral processing engineers as pollution experts, to pinpoint some specific problems encountered in different phases of processing, to discuss in some

detail the environmental problems associated with the use of common and specific flotation reagents, to examine the effect of hazardous metallic ions in plant effluents and to plead for the incorporation of environmental awareness and training as integral parts of mineral engineering curricula.

MINERAL PROCESS ENGINEERING AND POLLUTION CONTROL

Since the art and science of metallurgy deals in the separation of valuable material from waste products either in the solid, liquid or gaseous form, it is easy to appreciate that mineral processing engineers have a special competence for understanding and remedying pollution situations. The same basic principles that govern metallurgical processes also control pollution abatement technology, and most of the common processing machinery can be applicable to pollution problems. Classifiers, cyclones, electrostatic precipitators, thickeners, flotation cells or aerators, digesters, filters, extractors, and the like are all mineral processing units that have found specific applications in pollution control schemes.

According to Aplan[5] the essence of mineral process engineering consists of particle technology, applied surface chemistry, and chemical dissolution which are also basic elements of a pollution control program. Furthermore, the technology of solid waste disposal, recovery of secondary metals and recycling all depend on the unit operations and processes that are the basis of separation of metals and minerals from their ores. A typical flowsheet proposed by Sullivan *et al.*[6] for waste disposal as illustrated in Figure 10 clearly reveals that it is comparable to the flowsheet for recovery of minerals from their ores.

For these reasons, it is up to the metallurgists and mineral processing engineers to pave the way for improvements and innovations in the pollution abatement technology and to share their knowledge with environmental engineers in providing the badly needed mineral resources and metals with a minimum degradation of the environment. Also for these reasons, there is no excuse for the absence of abatement systems in mill design and the existence of pollution and environmental problems in processing plant operations.

Figure 10. Physical beneficiation flowsheet for concentrating valuable materials contained in incinerator residues (according to USBM).

ENVIRONMENTAL EFFECTS OF FLOTATION PROCESSING

Froth flotation is the most widely used technique for the recovery of valuable minerals from ores. In this process, the disposal of the solids in the tailings and the residual reagents and soluble metal ions and complexes contained in the liquid portion of the tailings constitute the major pollution problems.

The task of controlling and abating the extent of pollution problems from a flotation circuit should be critically evaluated during laboratory-pilot plant testing. The mineral processing engineer designing or evaluating a given flotation operation should consider critically not only the per cent recovery, concentrate grade and overall reagent costs, but also the environmental problems associated with each flotation scheme.

In the future, it is anticipated that most of the water control boards and environmental protection and improvement agencies will demand environmental position or feasibility reports not only from newly proposed flotation plants but also from operating plants.

The major contributors to the pollution problems in the flotation plant are the rather noxious reagents used in the process. These include a wide variety of collectors, frothers, depressants, activators, and modifiers. Such organic and inorganic reagents constitute hazardous pollutants in ground or surface waters due to flotation effluents in the soil, breakage of tailings dam or pipelines, and accidental spills.

The pollutants contained in the aqueous portion of the tailings may be grouped into two major classes: first, the residual organic and inorganic reagents added deliberately to the flotation circuit to recover the valuable minerals, and second the light and heavy metal ions and complexes contributed to the aqueous phase by the ore itself due to partial solubilities of various minerals in water and/or to their dissolution by some of the flotation reagents.

EFFECT OF FLOTATION REAGENTS

A critical examination of Table XII reveals the following observations concerning the residual reagents contained in the aqueous portion of the tailings:

Table XII

Environmental Considerations for Common Flotation Reagents

Reagent Type & Name	Chemical Composition	Amount Added	Reagents Distribution: Solids	Reagents Distribution: Solution	Toxic Species
Collectors					
Xanthate	$ROCSSH$	<0.1	Mostly complexed	Minor	CS_2
Thiophosphates	$(RO)_2PSSH$	<0.1	Mostly complexed	Minor	$H_2PO_4^-$, HS^-, H_2S
Fatty acids	$RCOOH$	0.5 to 2.0	Complexed with minerals and ions	Minor	Biodegradable
Sulfonates and Sulfates	RSO_3H RSO_4	0.5 to 2.0	Complexed with minerals and ions	Minor	Biodegradable (except Cyclic)
Amines	RNH_2Ac	0.2 to 2.0	Adsorbed on silicates	Minor	Free amine*
Fuel oils	Saturated	0.1	Selectively adsorbed	Minor	Volatile hydrocarbons
Frothers					
Pine oil	Aromatic alcohols	< 0.1	Carried over in froth	Appreciable	Volatile, carcinogenic
Dow froth	Higher alcohols	< 0.1	Carried over in froth	Appreciable	Volatile, biodegradable
MIBC	Methyl isobutyl-carbinol	< 0.1	Carried over in froth	Appreciable	Volatile, biodegradable
Conditioners					
Sodium sulfides	Na_2S, $NaHS$	1 to 15	Selectively complexed	Major	HS^-, H_2S, $SO_4^=$
Phosphorus Pentasulfide	P_2S_5	1 to 4	Selectively complexed	Major	HS^-, H_2S
Sodium Cyanide	$NaCN$	0.005 to 0.1	Mostly complexed	Minor	CN^-
Sodium Silicate	Na_2SiO_3	0.2 to 1.0	Mostly complexed	Appreciable	H_4SiO_4
Milk of Lime	$Ca(OH)_2$	1 to 4	Mostly complexed	Appreciable	OH^-
Separan	Polyacrylamid	<0.01	Mostly adsorbed	Minor	Biodegradable

*Unknown toxicity.

1. The amounts of flotation reagents used in the process are very small and kept at a minimum (starvation levels) not only because of economics but also to avoid the detrimental effects of excess reagents on the flotation results and water quality of the plant effluents.
2. Most of the added reagents are more or less completely consumed during the flotation process due to adsorption onto the mineral surfaces or complexing with appropriate ions in solution.
3. The trace amounts of some organic reagents, such as hydrocarbons, alcohols, and esters, remaining in the tailings water evaporate, decompose or biodegrade.
4. In general, inorganic reagents contribute either active cations or anions that react at the mineral surfaces or in the aqueous phase, leaving one or the other in the tailings liquid. Since most of these cations or anions are always present in streams and natural ground waters, they do not act as pollutants in the small amounts added to the flotation systems.

From these observations it is evident that the limited amounts of several reagents added to the flotation circuits are almost completely consumed or complexed in the process or are eliminated or decomposed during the impounding of the tailings. Therefore, in general, they do not contaminate the decant water discharged into the stream, river or lake, nor do they pollute the ground water due to seepage.

However, some toxic reagents if used indiscriminately or carelessly in the flotation systems can constitute a major water pollution hazard and even a fatal pollutant under plant operating conditions. Cyanide and hydrogen sulfide are two such reagents that need a more detailed scrutiny. These reagents are widely used in sulfide flotation systems, especially in the selective flotation of molybdenite from copper concentrates. Because of their extremely toxic nature to man, animals and aquatic life, they have been under investigation by the state and federal environmental protection agencies.

Davis[7] has thoroughly covered the topic of control of water pollutants from flotation plants.

The common methods proposed for the treatment of flotation plant effluents prior to their discharge in streams, rivers, lakes or ground water are chemical alteration and precipitation, coagulation and sedimentation, activated charcoal adsorption, biological treatment, filtration, and foaming. In addition to these, the processing engineers should consider some of the newly developed methods such as ion exchange, reverse osmosis and electrodialysis.

The Cyanide Problem

Wright and Bhappu[8] have discussed the environmental problem associated with the use of cyanide in flotation circuits. The primary reason for adding sodium cyanide to the molybdenite flotation circuit is to depress pyrite and other gangue sulfide minerals in the ore so that they will not float along with the molybdenite. This depressing action of cyanide is due primarily to the formation of extremely stable water-wettable complexes with heavy-metal cations in two stages: first, precipitates of relatively insoluble cyanide salts form, and second they dissolve in excess cyanide to form cyanide complexes.

For example, the cyanide ion reacts with the ferrous ion in aqueous solution to form the complex ferrocyanide ion $[Fe(CN)_6]^{-4}$. A similar complex forms with ferrous ions present on the pyrite surface, thus depressing pyrite in the selective flotation of molybdenite. Corresponding cyanide complexes also form on the copper and zinc sulfides if present in the ore.

In flotation systems, the effect of alkali cyanide additions to depress gangue sulfides depends to a large extent on the pH of the system. Sodium cyanide hydrolyzes in aqueous solutions to form free alkali and hydrogen cyanide, relatively insoluble in water:

$$NaCN + H_2O \rightleftarrows HCN + NaOH \qquad (1)$$

According to this equation, the presence of free alkali in solution shifts the hydrolysis to the left. Since the concentration of CN^- determines its availability for depression of gangue sulfides, a higher pH favors its depression effect (see Table XIII).

Besides complexing with heavy-metal cations on the surfaces of the minerals as well as in the

Table XIII

Influence of pH on Relative Abundance of CN^- Ions and Dissolved HCN[9]

pH	Millimole/millimole Total Alkali Cyanide As CN^-	As HCN
6.0	0.0005*	0.9995
6.5	0.0015	0.998
7.0	0.0047	0.995
7.5	0.0146	0.985
8.0	0.045	0.955
8.5	0.129	0.871
9.0	0.320	0.680
9.5	0.597	0.403
10.0	0.825	0.175
11.0	0.979	0.021
12.0	0.999	0.001
13.0	1.000	0.000

*To obtain the CN^- in milligrams per milligram of sodium cyanide, it is sufficient to multiply the numbers in this column by 0.531.

solution, cyanide also has a tendency to dissolve sulfide minerals of copper, zinc, and iron. The end products of these reactions are the corresponding metal cyanides, thiocyanate, and sulfate. For example, pyrite reacts with cyanide thus:

$$FeS_2 + 7NaCN + 2O_2 = Na_4Fe(CN)_6 + Na_2SO_4 + NaCNS \qquad (2)$$

From this discussion, one can see that the cyanide added to the flotation system should be used up in complexing with metal cations on the mineral surfaces and in solution or in forming thiocyanate. Also, because of the presence of appreciable amounts of gangue sulfides as well as heavy-metal cations in the flotation plant feed and tailings, no free CN^- should remain in tailings water. The only cyanide products that could be present in the tailings water would be complexed heavy-metal cyanides and thiocyanate.

Table XIV gives average analyses for free cyanide, thiocyanate, ferrocyanide, sulfide, phosphorus, and metal ions present in the plant effluents from several flotation plants in which molybdenite is selectively floated from copper concentrates with the use of sulfides and cyanides. The results clearly indicate that no free cyanide remains in any of the plant effluents, except a very small amount of free cyanide in the reclaimed water that is recirculated in the plant.

Table XIV

Average Analyses of Effluents from Selective Sulfide Flotation Plants

	Plant Tailing	*Reclaimed Water*	*Tailing Discharge*
	(all values in ppm)		
Cu	0.01	0.01	< 0.01
Zn	0.02	0.05	0.03
Pb	0.07	0.10	< 0.01
Fe	0.05	0.20	< 0.05
Mn	0.50	0.90	0.10
Ca	71.0	65.0	31.0
Mg	17.5	16.0	6.0
Mo	3.0	3.8	0.0
Cn	< 0.005	< 0.005	N.D.
SCN	0.10	0.12	N.D.
Fe(CN)	N.D.	N.D.	N.D.
$S^{=}$	N.D.	N.D.	N.D.
P	N.D.	< 0.01	< 0.01

N.D. - none detected

Therefore, the limited amount of cyanide added to the flotation systems does not constitute a hazardous condition either at the mill or in the plant effluent. The only way in which free cyanide can remain in the tailings effluent is if it is added in excess, a condition that should never be

allowed to exist in an efficient and safe flotation plant.

In recent years, the removal of residual cyanide from waste effluents has received much attention. Most of the published literature is concerned with the treatment of spent solutions from electroplating plants.[10] Methods for cyanide removal include oxidation processes (with Cl_2, NaOCl, O_3, H_2O_2, and electrolysis), ion exchange formation of insoluble cyanide complexes acidification-aeration process, and biological decomposition.

Hydrogen Sulfide Problem

Alkali sulfides have been used extensively in flotation systems both as activators (for oxide or tarnished sulfide minerals) and depressants (for depressing gangue sulfides in selective flotation of particular sulfide minerals). These systems have been critically examined by Cox *et al.*,[11] Gaudin[9] and Dudenkov *et al.*[12] Theoretical work suggests that the actual depressant is the hydrosulfide ion, HS^-, rather than sodium sulfide or hydrogen sulfide.

An examination of Table XV reveals that the availability of HS^- ions increases with increasing pH up to 9.0 after which the concentration of the ions remains more or less constant. Therefore in order to obtain maximum benefit of the reagent, the flotation should be carried out at higher pH values.

From environmental and safety considerations, the major factor to watch for is the liberation of H_2S in the flotation system. Although the solubility of H_2S in water is relatively high (0.12 m/l at one atmosphere), under the existing flotation conditions there are good possibilities for evolution of H_2S, thus causing a hazardous operating condition. It is fortunate that sufficient dilution of H_2S with fresh air takes place in most of the operating plant to keep its concentration below the threshold level. Nevertheless, the problem does exist and efforts should be made to keep down the H_2S concentration through suitable operating controls and proper ventilation.

The toxicity of H_2S is greatly underrated. In sewage disposal, 1 ppm of sulfide under certain conditions (mostly acidic) causes a most lethal atmosphere.[13] Lethal concentrations for H_2S are similar to those for hydrocyanic acid. However, the latter is more soluble in water and thus somewhat less hazardous.

Table XV

Relative Abundance of H_2S, HS^- and $S^{=}$ as a Function of pH[9]

For every millimole $Na_2S \cdot 9H_2O$ added per liter, there is

pH	*Dissolved H_2S (millimole/liter)*	*Dissolved HS^- (millimole/liter)*	*Dissolved $S^{=}$ (millimole/liter)*
4.0	1.0	0.0010	2×10^{-14}
4.5	1.0	0.0030	2×10^{-13}
5.0	0.99	0.010	2×10^{-12}
5.5	0.97	0.030	2×10^{-11}
6.0	0.91	0.09	2×10^{-10}
6.5	0.75	0.25	1.6×10^{-9}
7.0	0.50	0.50	0.5×10^{-8}
7.5	0.25	0.75	6.5×10^{-8}
8.0	0.09	0.91	2×10^{-7}
8.5	0.030	0.97	7×10^{-7}
9.0	0.010	1.00	0.000002
10.0	0.0010	1.00	0.00002
11.0	0.00010	1.00	0.0002
12.0	0.000010	1.00	0.002
13.0	0.000001	0.98	0.02
14.0	0.0000001	0.80	0.20

Since the concentration of H_2S is dependent on the pH, the safest as well as the most effective method in the plant is to try to maintain a high pH in the flotation circuit with the use of caustic. This is especially true for those circuits using Nokes' reagent containing phosphorus pentasulfide (P_2S_5). The most critical phase of the use of this reagent is in the preparation of Nokes' solution for plant use. It is imperative that ultimate precautions be taken in the mixing step to make sure that all the P_2S_5 has reacted with caustic and that the solution is stabilized. If equilibrium is not reached, decomposition of the reaction product can occur, giving off H_2S.

The optimum conditions can be met by digesting P_2S_5 slowly in at least a 10% excess caustic over the stoichiometric requirement. Since the reaction is exothermic and since the decomposition of the reaction product is enhanced at higher temperatures, precautions must be taken to keep the temperature down, preferably below 120° F. Provisions should also be made to have available at the mixing tank a source of caustic so that, if needed, it can be added to the mixture to prevent its decomposition. Additional safety devices such as alarm systems based on H_2S detection should also be installed at strategic locations and operators should be trained to avert a possible disaster.

Hazardous Metallic Ions in Plant Effluents

As pointed out earlier the mill tailing water contains several light and heavy metal ions and complexes that are normally contributed to the system due to natural solubility of valuable and gangue minerals contained in the ore. Some of these dissolved metals such As, Cr, Hg, Pb and Se constitute serious pollution problems and are considered "hazardous substances" by the environmental protection agencies.

In order to prevent the degradation of the environment and injury to man, animals, and aquatic life, the government agencies have adopted "regulations" concerning the discharge of hazardous substances. Typical regulations adopted by the New Mexico Water Quality Control Commission on August 27, 1971, are as follows:

Regulation Number 6 - Discharge of Hazardous Substances

A. No person shall cause or allow effluent from a new process or plant to discharge directly or indirectly into water as defined by the Water Quality Act unless the effluent, as indicated by any single sample, conforms to the following:

Arsenic	0.05 mg/l or less
Barium	1.0 mg/l or less
Boron	0.75 mg/l or less
Cadmium	0.01 mg/l or less
Chromium (Total)	0.01 mg/l or less
Copper*	0.05 mg/l or less
Lead	0.05 mg/l or less

Manganese	0.1 mg/l or less
Mercury	0.001 mg/l or less
Molybdenum	0.01 mg/l or less
Nickel	0.1 mg/l or less
Selenium	0.01 mg/l or less
Silver	0.05 mg/l or less
Zinc*	0.1 mg/l or less

*Provided that effluents from a community sewerage system may contain 0.1 mg/l copper and 0.5 mg/l zinc.

B. Subsection A does not apply to constituents in the water diverted. Samples shall be examined in accordance with the latest editions of Standard Methods for the Examination of Water and Wastewater published by the American Public Health Association, or Methods for Chemical Analysis of Water and Wastes published by the Environmental Protection Agency, where applicable.

Regulation Number 4 - Effluent Quality

A. Except as otherwise provided in this regulation, no person shall cause or allow effluent to discharge directly or indirectly into water as defined by the Water Quality Act unless the effluent:

1. as indicated by any daily composite sample, conforms to the following:

Biochemical Oxygen Demand (BOD)	less than 30 mg/l
Chemical Oxygen Demand (COD)	less than 125 mg/l
Settleable Solids	less than 0.5 ml/l

2. as indicated by single sample, conforms to the following:

Biochemical Oxygen Demand (BOD)	less than 160 mg/l
Chemical Oxygen Demand (COD)	less than 250 mg/l
Settleable solids	less than 1.0 ml/l
Fecal coliforms	less than 500 organisms/ 100 ml
pH	between 6.7 and 8.6

Upon application, the Director of the Environmental Improvement Agency may eliminate the pH requirement for any effluent source that the Director determines does not unreasonably degrade the water into which the effluent is discharged.

As mineral process engineers we can appreciate the primary reasons for the very low concentration of metallic ions in tailing effluents. First, the solubility of many naturally occurring minerals (sulfides, oxides and silicates) is limited. Second, most of the dissolved metallic ions tend to hydrolyze at higher pH values normally used in the flotation systems and since the solubilities of most of the metal hydroxides are limited (see Table XVI), the ionic concentrations are correspondingly low (well below the specified regulations). Moreover, some of the metal ions such as Mo, W and V complex with calcium (available through lime addition to the flotation circuit) to form very insoluble compounds such as $CaMoO_4$ and $CaWO_4$. Finally, many light and heavy metallic ions are complexed with flotation reagents (collectors, depressants and modifiers) to form insoluble complexes. The end result of all these chemical reactions in the flotation system is the depletion of hazardous ions in the tailing effluents.

In the event that concentrations of hazardous ions in the plant effluent are above specified limits, then water must be treated to comply with the regulations. Methods commonly used in the tertiary treatment of municipal waters and abatement of pollutants in industrial effluents can be readily applicable to the treatment of mill effluents. These include neutralization, chemical alteration and precipitation, charcoal adsorption, ion exchange, biological treatment and foam flotation.

The above discussion clearly indicates that with proper understanding of the mineral-chemistry, surface-chemistry, ionic equilibria and the flotation mechanisms coupled with the abatement technology, it should be possible to economically remove hazardous substances from plant effluents. Certainly, the technology and the proper incentives are available to the mineral process engineers to operate economically without polluting the environment.

Table XVI

Solubility of Selected Minerals, Precipitates and Organo-Metallic Complexes

Minerals or Compounds	*Solubility in Water (ppm)*	
	Cations	*Anions*
Cu_2S	2.2×10^{-14}	5.4×10^{-12}
CuS	1.9×10^{-7}	9.6×10^{-9}
PbS	5.8×10^{-4}	9.0×10^{-10}
HgS	1.26×10^{-21}	2.0×10^{-23}
NiS	3.2×10^{-5}	1.7×10^{-5}
ZnS	2.0×10^{-6}	1.0×10^{-6}
$PbWO_4$	12	5.7
$PbSO_4$	0.8×10^{3}	0.38×10^{3}
$CaCO_3$	3.7×10^{3}	5.6×10^{3}
CaF_2	8.6×10^{-3}	8.2×10^{-3}
$Ca_3(PO_4)_2$	8.4×10^{-4}	1.26×10^{-3}
$CaSO_4$	0.52×10^{3}	1.26×10^{3}

	Hydrolysis Product (Ksp)	*pH of Precipitation*
$Fe(OH)_2$	1×10^{-15}	7.0
$Fe(OH)_3$	1×10^{-38}	3.0
$Al(OH)_3$	1×10^{-32}	4.2
$Cu(OH)_2$	1×10^{-20}	5.5
$Mg(OH)_2$	6×10^{-12}	10.5
$Ca(OH)_2$	8×10^{-6}	11.5

	Solubility Products (Ksp)
Zn - ethyl xanthate	5.3×10^{-9}
Pb - ethyl xanthate	6.7×10^{-16}
$Ca(Ol)_2$	3.9×10^{-13}
$Mg(Ol)_2$	1.6×10^{-11}
$Ba(Ol)_3$	1.3×10^{-12}
$Fe(Ol)_2$	3.9×10^{-13}
$Mg(RSO_3)_2$	10^{-8} to 10^{-11}
$Ca(RSO_3)_2$	10^{-8} to 10^{-14}
$Fe(RSO_3)_2$	10^{-18} to 10^{-21}
$Al(RSO_3)_2$	10^{-16} to 10^{-18}

NEED FOR ENVIRONMENTAL AWARENESS AND TRAINING

It is obvious that the mineral process engineer of today and the future has to play a dual role, that of a metallurgist as well as environmentalist. Traditionally, he is trained in the basic sciences and engineering common to both fields. What is needed is a keen awareness and concern to fulfill the dual responsibility that our mineral-based society has imposed on him.

This awareness and technical competence can only be developed through a realistic and well-balanced engineering curriculum. It is not necessary that the undergraduate engineer be required to take a specific course or courses in environmental science and engineering. However, it is essential that the student be made aware of the similarities in the two fields throughout all the engineering courses. With proper orientation and a minimum of deviation an instructor can do an adequate job of training the mineral process engineer so that he will be in a position to solve the environmental problems facing him in his professional career.

INTRODUCTION

Only recently have mining companies begun to see water management as a critical issue for gold and silver recovery, that is except for the mechanical engineering aspects of pumps, pipes, valves and storage tanks. Water needs for mining gold and silver have even in bygone eras resulted in ingenious means of supplying water to gold and silver recovery facilities. This brings to mind the ingenious U-tube transportation of water from Lake Tahoe on the southern side of the Reno Valley to Virginia City on the northeastern side of the valley which required no pumping. The 27 mile long 4 inch diameter pipeline built in 1882 to furnish water from the White Mountains for the mills and town of Candelaria was hand riveted in Scotland and shipped across the Atlantic and around Cape Horn by sailing vessel. Another mammoth project supplying water to gold and silver operations is the pipeline built from Mundering Weir near Perth in Western Australia to Kalgoorlie and the goldfields that are the basis for the town's existence, a distance of 600 kilometers away.

A questionaire was sent to about 200 gold and silver mines and mills enquiring about water use and management practices in the main gold mining districts of the world. The responses to this questionaire have been summarized in a table at the end of Chapter 3 and in a summary extract inserted below.

MOTIVATION

Motivation for today's water management practices include:

- Shortage of water.
- Excess of water both underground and precipitation.
- Meeting permit requirements.
- Cost of water.
- Quality of water.
- High cost of reagents and the need to recycle them.
- Contaminants in ores, concentrates and calcines.
- Environmental constraints.

CLIMATIC INFLUENCE

The approach to water management for gold and silver recovery operations varies markedly to meet site specific needs. Climatic influences are one of the most important.

Desert Climate = Shortage of water or poor quality of groundwater. Net evaporation allows zero discharge operaions.

Extreme Cold Winters = Need to contain tailings and effluents without decant recycling through the frozen months. Need for an unfrozen water supply. No natural cyanide degradation in winter.

Tropical Climate = Excess precipitation for outdoor heap leaching. Wet or very wet seasons.

Regulatory Climate = Varies from highly supportive encouragement to downright discouragement and obstructionism.

Modern water management in gold and silver mining operations has come a long way but remains at a low point on the learning curve. Water management will be the mother of technical invention. For example, in the People's Republic of China a thiourea leaching circuit employing an iron in pulp recovery process was developed because of feared toxicity effects if cyanide were to be used so close to the capital Beijing (Peking). Other examples are the new biological water treatment process for removal of cyanide, metals, thiocyanate and ammonia developed by Homestake Mining Company; water effluent equipment and circuits etc. Anticipated higher costs of fresh water in South Africa, Western Australia and elsewhere will undoubtedly stimulate further innovations.

Some observations concerning water management for gold and silver recovery at the main gold and silver producing countries of the "free" world are commented on below.

Summary of available data on net water consumption by gold and silver recovery operations gathered in an industry-wide survey is provided in the table overleaf. From this it appears that:

1) Water consumption in gold and silver recovery operations expands to need the amount available.

2) Heap leaching requires 0.15 - 0.50 m^3 net new water per ton ore which is much less than needed for conventional milling. Further refinements could lead to still greater water efficiency.

A critical aspect of water management in estimating the water needs of an operation where water is in short supply is to be sure to take seasonal fluctuations in both the water consumption needs and the source of supply into account.

If the average needs of a heap leaching operation of say 1000 tons per day are 0.20 m^3 water per ton ore, this means that a source of 37 USgpm will be required. However, at the height of the summer the actual daily needs may increase to 0.5 - 0.6 m^3 water per

ton solids requiring a supply of 100 US gpm. The time when the maximum water supply is needed, also coincides with when the water supply may be at its lowest.

Likewise, it is possible to select different types of sprinklers for solution application as a means of conserving water when necessary, e.g., direct application of solution without sprays or by using a solution mist sprayer to enhance evaporation when the water inventory is too high. In this way water consumption for one operation can be manipulated between 470 US gpm to 800 US gpm as a water balance managing tool.

WATER CONSUMPTION FOR GOLD AND SILVER RECOVERY

	Tons Milled	Net Water Consumption	m^3 Water/ Ton Ore

South Africa

The Witwatersrand has supplied forty percent of the gold ever mined in the world and currently accounts for 67% of free world gold production, concentrated around the edge of an underground basin perhaps 300 X 200 km in extent.

In South Africa the overall shortage of water and associated medium term water quality projections in the industrial heartland of the country centered around Johannesburg

have become a matter of national urgency. A recent study of demographic, socio-economic and industrial growth projections revealed that the availability of suitable water will be a serious limiting factor. A second study by HEYNIKE (1983) investigated the cost to the economy resulting from further buildup in total dissolved solids in the main water supply and concluded that the steady buildup of TDS must be arrested and if possible reversed.

Many of the gold mines and mills have associated byproduct uranium recovery plants. To generate sulfuric acid for uranium leaching, pyrite is floated from gold-uranium ore and tailings and roasted. Gold is also recovered by leaching the calcine. The industry is characterized by very large hot and deep, labor intensive mines and multiple integrated mine-mill complexes. Typical mill capacities are 100,000-300,000 tons per month although some are larger. The ERGO tailings retreatment facility treats 1,500,000 tons per month of reclaimed tailings. The VAAL REEFS complex treats 9 million tons per year of underground ore. KEMPE (1981) estimated that from 1884 to 1980 a total of 37 billion tons of ore had been treated on the Witwatersrand.

Macro Problem

The gold industry of the Witwatersrand is located east, west and south of Johannesburg, which is also the industrial hub of South Africa with major metropolitan concentrations totaling over 1.6 million.

The climate is characterised by dry winters and convection rainfall in summer. The whole area draws its water from the Vaal River and Vaal Dam and there is a macro recycling loop in effect. Very little water actually leaves the Vaal River along the natural drainage into the Orange River and in fact serious consideration is being given to reversing the flow of the Vaal River to draw water into the system instead of the present drainage from it. This water is settled and treated before distribution by State owned regional water authorities such as the RAND WATER BOARD, OFS WATER BOARD, and the WEST RAND WATER BOARD.

Summer precipitation over much of the area comes in torrential downpours associated with thunderstorms and drains into the Vaal Dam and the Vaal River via a host of tributaries. It has been found that dissolved salts that cannot be removed economically by conventional water treatment e.g., precipitation, are building up in the Vaal Dam water. A number of industries have been identified as point source contributors of dissolved solids in effluents that eventually drain to the Vaal River. One of the major point source contributors is the gold and uranium mining and milling industry. The most obvious of the point sources is underground mine drainage water which is pumped to the surface from some of the deeper mines such as East Rand Proprietory Mines Ltd. (ERPM) and S. A. Land & Exploration Co. Ltd. (SALLIES) which are points from which underground mine water draining from large areas of mineworkings in the east rand (east of

FIGURE 15 SCHEMATIC DIAGRAM OF STUDY AREA SHOWING MAJOR POINT DISCHARGES: OCT 1977 - SEPT 1982 FLOWS ($m^3 \times 10^6$) AND LOADS (t)

Johannesburg) are pumped. In Witwatersrand stopes, mine water comes in contact with sulfide minerals in the presence of air at relatively high temperatures and becomes acid on account of the oxidation of pyrites to sulfuric acid. There may also be some seepage of high TDS solutions into the mineworkings. On neutralization this underground water has relatively high levels of $SO_4^{=}$, Ca^{++}, Cl^{-}, Fe^{++}, ec. and a tds level approaching 3,000 mg/l.

A major study has been carried out by a firm of consulting engineers in South Africa for the Dept. of Environment Affairs which quantitatively shows the relationship of mining industry point source effluents in relation to that from other industries. A summary of this so-called GREEN REPORT has also been prepared. Further information could be requested from the authors or possibly from the Dept. of Environment Affairs.

DEPARTMENT OF ENVIRONMENT AFFAIRS
Private Bag X313
Pretoria 0001
(012) 268-402
Mr. Hendrik J. Best

This report does not discuss the impact of the West and Far West Rand gold and uranium operations on the water of the Vaal River, nor the Orange Free State Goldfields impact on their local water supply. For the southern PWVS region the mean annual intakes, and discharges in the Vaal Dam catchment area from 1977 to 1982 were as follows:

	Municipalities	Industries	Mining and Milling	Total
Water Supplied (10^6 m^3/yr)	329	136	68	533
Effluent Discharged (10^6 m^3/yr)	244	63	43	350
Percentage Returned	74	46	63	65
TDS Load Discharged (tpa)	160,200	97,100	129,400	386,700
Mean Effluent Concentration (mg/l)	660	1,550	3,000	1,100

Emergency measures to conserve water and the quality of the public water supply to the PWVS area are being called for on account of the drought. These will be very expensive and represent an economic burden on the mining industry and ultimately the country.

FIG. 2. ANNUAL RAND WATER BOARD ABSTRACTION FROM VAAL SYSTEM 1935 TO 1979 AND PROJECTED ABSTRACTION 1980 TO 2000.

PAST AND PROJECTED AVERAGE ANNUAL TDS CONCENTRATION AT THE RAND WATER BOARDS VEREENIGING INTAKE

FIG. 3.

Industrial use and impact on water quality has become so great that it has now become unrealistic to hope that when the present climatic cycle shifts to a high rainfall phase, the volume of drainage will increase and the Vaal Dam will overflow releasing large quantities of high TDS water ultimately to the Atlantic Ocean to the extent that Vaal Dam salt load will be adequately reduced.

Unfortunately, the statistical evidence of TDS in the Vaal reported by HEYNIKE & McCULLOCH (1983) are quite conclusive in showing that climatic cycles over the last fifty years have not been able to arrest the marked increasing trend in this salt load, as industrial and municipal demand and impact on this water reservoir steadily grew.

It was observed that the quantity of water received by the gold mines included water pumped from the mines and a comparatively small volume of water obtained from the Rand Water Board or other above ground sources. These mines however discharged about 34% of the point source TDS load in only about 12% of the effluent volume. This last estimate has caused the mining industry to become one of the primary targets of the Dept. of Environment Affairs in their primary objective of reducing TDS buildup in Vaal water.

The gold and uranium ore treatment process (and there are several variations in the way uranium and gold processes are integrated) require several sequential pH changes. For example, consider a mill using acid mine water in a "forward leach" configuration:

1) Neutralization of acid mine water (pH 3.5).
   Precipitation of gypsum, $Fe(OH)_3$, etc.

2) Addition of lime to pH 10 in gold extraction plant.

3) Chemicals in eluate from CIP plant after gold recovery.

4) Reduction of pH - Acid addition in uranium leach.

5) Use of acid in the SX strip plant.

6) Addition of lime to neutralize tailings and raffinates before pumping to tailings.

Numerous processing steps each add to the salt load. However, considerable quantities of precipitate are settled and left in the tailings impoundments.

Because of the acute water shortage over the last three summers (1981, 1982 & 1983) the mining companies were all obliged to cut back on their water consumption. The fact that without any real hardship they were readily able to reduce their fresh water intake by about 30-40% indicates that hitherto not very much effort had been needed in this

MILL TAILINGS IN JOHANNESBURG

SINKHOLES AT A MINE TOWNSHIP WEST OF JOHANNESBURG

direction. Some of these mining and milling complexes in 1984 still do not know the precise details of their internal water balance. One complex consists of several gold and uranium mills and associated mines and its 1984 budget, just to quantify internal and external water balances, was around R500,000.

To the west of Johannesburg gold ore is overlain by dolomitic sedimentary rocks divided into separate virtually water tight compartments by dikes. Natural groundwater stored in these dolomitic aquifers is of excellent quality and it is established that they could potentially be used to store excess water during times of plenty and then serve as a supplementary supply during dry years.

Several mines are located to the west of Johannesburg with milling operations located at surface over the dolomites. These include mines such as Randfontein Estates Gold Mining Co.; Venterspost G. M. Co. Ltd.; Elandsrand; Deelkraal; West Rand Consolidated G. M. Co. Ltd.; Westernareas G. M. Co. Ltd.; West and East Driefontein; Kloof G. M. Co. Ltd.; etc. The mines have three potential effects on the dolomitic aquifers:

1) Many of the mines pump huge amounts of water to the surface to dewater their underground workings. This has resulted in a lowering of the water table and a severe sinkhole problem in the farming areas around some of the mines.

2) Tailings dams, wasterock piles, tailings solution reclaim ponds and evaporation ponds are seldom lined and seepage from these into groundwater may add significantly to dissolved solids in groundwater, some of which may migrate back to the surface or into underground workings. It is fair to note here, however, that many tailings dams are constructed on a naturally occurring black clayey silt of limited permeability. Modern slimes dams are designed to catch surface runoff for evaporation in ponds which are also usually not lined and may contribute.

3) Recirculation of minewater which is often reinjected into the dolomites at some distance from the mine and partly finds its way back to the underground workings results in an uptake of further TDS due to oxidation of stopes underground.

All around the Witwatersrand even in the outskirts of Johannesburg there are huge tailings heaps. Runoff and seepage, especially from the older sand tailings and wasterock piles that contain pyrite and significant quantities of $CaSO_4$ and leachable iron undoubtedly contribute significantly to the dissolved solids that enter both the surface waters draining to the Vaal and also the groundwater that drains into the dolomitic aquifers 20 miles west of the city. The effect of water draining from and seeping through mine tailings dumps and wasterock piles is currently under study and the results will not be known until 1986.

However, visual inspection of the area from the air gives a pretty good qualitative idea of how the results of these investigations may turn out.

The investigation of seepage and runoff contamination from several tailings dams of different ages and wasterock piles is being undertaken by:

SUMMARY OF MACRO PROBLEMS - SOUTH AFRICAN GOLD AND URANIUM INDUSTRY

The mining industry on the Witwatersrand is being pressed to achieve the following:

1) Reduce fresh water intakes.
2) Minimize dissolved solids in point source effluents.
3) Reduce dissolved solids loss to groundwater to preserve the quality of potentially usable aquifers.

If, on account of restricted use of fresh Rand Water Board Water, some of the mine-mill complexes located over dolomitic aquifers are obliged to use more underground minewater and to recycle more tailings reclaim solution, then it is conceivable that the dolomitic water (currently already at 1,000-1,500 ppm TDS in places) may locally deteriorate further even to above the SABS allowable drinking water standard of 2,000 ppm tds. In such an event there could be a potential conflict with the law, especially the Water Act as recently ammended as discussed in Chapter 7 on regulations.

The WATER ACT, No. 54 of 1956 paragraph 23 is clear in its intent:

"Prevention of pollution of water.

23. (1) Any person who wilfully or negligently, and, where any provision of section twenty-one or twenty-two applies, contrary to that provision, does any act whereby any public or private water, including underground water, is polluted in such a way as to render it less fit for the purposes for which it is ordinarily used by other persons (including the Government, the South African Railways and Harbours Administration and any provincial administration) entitled to the use thereof, or for the propagation of fish or other aquatic life, or for recreational or other legitimate purposes, shall be guilty of an offence.

(2) (a) The Minister may out of moneys appropriated by Parliament for the purpose, take any steps which he may consider necessary to prevent the pollution, as a result

of seepage or drainage from any area on which mining or other industrial operations have been carried on, of public or private water, including underground water, after such operations have been abandoned, and may in his discretion recover the cost of any part of the cost incurred in taking such steps from any person who carried on or is entitled to carry on such operations.

(b) The Minister or a person acting under his authority may at any time enter upon any land for the purpose of taking any steps referred to in paragraph (a), and may take with him on to such land any men, animals, vehicles, equipment, appliances, instruments, stores or materials, and may erect such camps and construct such works as may be necessary for that purpose.

(c) No compensation shall be payable to any person for any loss which may be sustained by him in consequence of any action taken under this sub-section, except by order of a competent court."

Since the regulatory enforcement climate is currently in a state of flux in South Africa with respect to water conservation and effluent discharge and since the mining and milling water management practices at current operations were brought into production during times when water quality had not yet been recognized as an issue, mitigating measures may have to be adopted retrospectively in some cases.

South Africa - that is, the government, the people and industry are of course conscious of the important - actually vital - role of mining as the backbone of their economy. Mining was the main reason for the development of Johannesburg and neighboring cities in the first place. Current difficult economic conditions and high inflation may temper the regulatory ideals of the Dept. of the Environment for awhile. - However, since the need to conserve water and preserve its quality are also perceived as vital for the economy, it is clear that over the next 5 years there will be major changes in water management and water treatment practices on Witwatersrand gold and uranium mines and mills.

Historically mine-mill complexes could discharge effluent to surface water courses provided these effluents met a set of relatively easy standards. If they did not, then greater quantities of low cost fresh water were injected into the system. With RWB treated water available at R0.17 - R0.20/m^3 ($0.09 - $0.10/$m^3$) and untreated Vaal River water for those with access at R0.04/m^3, it was and still would be more cost effective to apply the well known idiom "The solution to pollution is dilution." This does not mean that the freshwater tap had to be opened directly at the effluent discharge point; the same effect can be achieved simply by using more fresh water in the milling operation. This measure could be supplemented by segregation of the worst quality effluents which could be pumped to the tailing dam or to ponds to be evaporated.

The Witwatersrand climate is one of net evaporation, and zero discharge is possible for most mine-mill complexes. Water balances of others are complicated by the need to dewater mines and discharge large amounts of water.

ALTERNATIVE WAYS TO REDUCE WATER CONSUMPTION AND CONTROL TDS RELEASE

In order to meet the three macro problems, the following list of alternatives is under consideration. Several additional ideas are mentioned. Since in the new regulatory climate and details of enforcement focus is still to be determined, much of the discussion is still speculative at this stage.

1) Reduction of Fresh Water Intake - Increased Recycling

This requires that greater internal recycle must be used. Through using more recycle water, the volume of effluent has been reduced in several operations. However, on account of recycling, TDS and contaminant levels could increase, except where large amounts of lime are used in conjunction with U-plant raffinates containing iron and aluminum which leaves at least some of the TDS in the tailings pond as a precipitate. See the trip report on Vaal Reefs in Appendix I.

Incentive to use less Rand Water Board water is expected to come in the form of a significant increase in the price of water from R0.17/m^3 to perhaps R0.75 - R1.00/m^3. Other restriction have been invoked such as stricter water use permits.

2) Use of Underground Minewater

The Chamber of is Mines developing a system whereby minewater pumped from underground is reused for the combined purposes of generating hydroelectric power underground and providing hydraulic power to operate underground drills etc.

Water used in the hydraulic powered tools must have a very low level of suspended solids which would otherwise result in severe abrasion costs. Research into the most effective means of removing suspended solids to the low levels required is receiving priority attention at the Chamber of Mines Research Laboratories.

On another front, it has been found that underground sludges are best settled underground and brought to the surface separately as clarified water and as thickener underflow sludge. Several improved underground settlers have been in use on the Witwatersrand. One, a cylindro-conical underground settler was developed by the CSIR under sponsorship by Anglo American Corp. and General Mining and subsequently improved by AARL. Platepack lamella settler clarifiers have also been introduced.

Earlier underground settlers were of horizontal design whereas the CSIR Cylindro conical units are vertical. Some discussion of the design of these units, flocculant selection and dosage is included in the chapter on solid liquid separation. In general it was found that some flocculants can achieve much lower turbidities at significantly lower cost than others ranging down to 0.5-1.0 cents per 1000 gallons.

CHAMBER OF MINES OF SOUTH AFRICA STATEMENT TO PRESS, JUNE, 1983

Water Restrictions

Members of the Chamber of Mines of South Africa and which fall in the areas served by the Rand Water Board, the Orange Free State Goldfields Water Board, and the Western Transvaal Regional Water Company reduced their use of water from the Vaal Dam by 18.3 percent during April in comparison with that month's consumption in the previous year.

In doing so, these mines which include practically all the large gold and platinum mines of South Africa almost met the appeal by the Minister of Environment Affairs and Fisheries on 8th March, that industries dependant on the Vaal Dam save 20 percent of the water obtained from that source.

The reduction has not affected production in any way--it being a condition of the mines' concerted water saving effort that production would be regarded as sacroscant.

The Chamber of Mines members have achieved a reduction of 106.3 megalitres a day in the water they obtain from Water Boards, mainly by cutting down on the use of water for domestic uses and by making greater use of water from sources other than the Vaal Dam.

For example, sewerage effluent from the Welkom municipality, which would otherwise have gone to waste, is now being used in the reduction process of gold mines in the vicinity in place of Vaal Dam water.

In other instances, hostel showers have had 30-second time switches installed, and water has been collected from every possible source, including slimes dams runoff.

The mines' options to save water have been considerably reduced over the years by repeated appeals. During the late 1960's, and on several subsequent occasions during similar water emergencies, all possible avenues to save Vaal Dam water were explored and implemented. At considerable cost, many mines duplicated reticulation systems so that their own underground water could be used in mineral process plants and for watering gardens and sports fields instead of water supplied from the Vaal Dam.

Resultant cuts in the use of Vaal Dam water have been as high as 28 percent and currently, most water used on mines is underground water occurring naturally in subterranean crevices or cavities. This water drains into the mines and is pumped to the surface but most often be treated at considerable expense before it can be used.

Other factors which make it difficult for the mining industry to reduce its dependance on Vaal Dam water include the big expansion in mining activity since the rise in the gold price in the early 1970's and particularly since 1980. To extend the lives of the gold mines, grade has been steadily reduced which means that more rock must be mined and milled to get the same output.

Water is the lifeblood of mining, and up to 2½ tons of water are required to mine a ton of ore. The quantity of ore treated by gold mines by members of the Chamber has increased from 73 million tons a year in 1972 to 95 million tons in 1982.

The past decade has also seen great progress in improving the environment underground which, in effect, means the use of more water to keep down harmful dust and to cool the underground workings. As mines go deeper, more and more refrigeration is necessary. This places a heavy demand on the use of high-quality water provided by sources served by the Vaal Dam. Another problem is that some of the new mines opening up are either relatively dry or in a transitionary stage and unable to capitalize on the water "make" underground.

In these circumstances, the savings achieved by the mines are most commendable, but the industry is far from satisfied, and many schemes to save Vaal Dam water are in the pipeline.

One of the most expensive is a scheme to pump underground minewater from one Orange Free State mine to another in the area, which can use this water. This pipeline scheme is to cost about R4 million. There are a number of other schemes costing anything between a quarter of a million rands and several millions of rands.

The Chamber's member mines were able to react quickly to the Minister's pleas because they had seen the water shortage writing on the wall already towards the end of last year and had started planning through Group Head Offices and through Chamber committees.

At the beginning of this year, Vaal Dam water consumption by mines, which had been rising steadily for some years, started to drop steeply and has done so ever since.

The savings achieved varies from mine to mine, with one large gold mine having cut its consumption of Rand Water Board water by 73% compared to the same period last year.

Some mines, often due to circumstances beyond their control such as rapidly expanding mining activity, are now using more Rand Water Board water than they were a year ago, but overall, the use of purified water from the Vaal Dam is down on mines in the area served by the O.F.S. Goldfields Water Board. For instance, in the four weeks ended 4th May, mines in this area reduced their Board water consumption by 24.3%.

The Chamber of Mines accepts that there is still room for improvement and thanks to the highly organized nature of the South African mining industry, further savings of purified water from the Water Boards can be expected in the future."

3) Use of Alternative Secondary Sources of Water

Use of tailings dam reclaim water and collected runoff in the mill or reclaimed treated sewage water from mine hostels or local municipalities. These may not be suitable for all process applications or may require special pretreatment as discussed in the previous chapter. At Vaal Reefs, there are five sewage treatment plants, all of which employ biofilters. After treatment, this water has been found satisfactory for use in gold and uranium recovery plants. Furthermore, with sophisticated further treatment, this type of water may even be used in flotation.

4) Lining of Tailings Dams, Wasterock Piles, Reclaim Water Ponds, and Evaporation Ponds

If and when tailings dams, evaporation ponds (sometimes located on top of tailings dams) and reclaim water storage ponds are established to be a cause of contamination of groundwater or useful aquifers, through seepage, then corrective measures may be required. Only those mines in sensitive locations would be affected from a contamination point of view. However, this measure would undoubtably save significant quantities of water that today go to waste.

Tailings dams

Old dumps consist of "sand" stamp mill tails which are porous and since many of these contain residual values, these are being reworked. Some do not have adequate values in them and represent a continuing source of acid mine drainage. Since the 1950's, all tailings disposed of have been "slimes" which are constructed in a form that has low permeability. However, some earlier slimes dams were poorly designed and were not maintained, resulting in erosion and distribution of AMD-generating material to the environment. The task of lining existing tailings impoundments may not be economically feasible.

The modern Witwatersrand approach to tailings disposal is to use a layered "dry" tailings disposal approach in which water is decanted from the surface and the lower

reaches of the dams drained through a system of underdrains. This approach avoids the hazards of a hydrostatic head against the dam walls and the enhanced seepage effects from dams with such a head. In this way most solution is segregated from the tailings which are essentially "dry." Decanted and underdrain collection water is stored in ponds for reuse or evaporation, and modern slimes dams are maintained on an ongoing basis. Better ways are constantly being researched. This technique results in a considerable evaporation loss.

Many of the older tailings dams are being reclaimed for secondary recovery and are then disposed of in more modern tailings dams equipped with underdrains. Pyrite is recovered by flotation from most tailings retreatment projects. This greatly reduces the AMD generating capacity of the residual materials as well.

The extent of seepage beneath tailings dams and of runoff water from tailings dams is still under evaluation. If serious enough it is possible that more extensive collection sytems will be required beneath the "dry" tailings dams, but the requirement to line tailings disposal sites is not anticipated.

Reclaim Water Ponds

Reclaim water storage ponds located over sensitive aquifers may require lining. Already some ponds perched on the banks of the Vaal River have been lined. These are mentioned below. Based on preliminary information the treated Bentonite linings are less expensive than plastic membranes. However, because bentonite is believed to fail in low pH conditions, the solutions must be neutralized first.

Evaporation Ponds

Evaporation ponds may become the least expensive way to dispose of excess contaminated solutions. When reclaim water ponds are lined, and if surface water runoff from wasterock piles, tailings etc. has to be impounded, the water balance of mine-mill complexes may require a bleed.

Evaporation ponds result in high TDS concentrations which would be particularly damaging to aquifers if lost through seepage. In sensitive locations, such ponds will likely need to be protected from leaks and seepage losses.

Wasterock Piles

Wasterock piles expose a large surface area of sulfidic materials to rain and air and undoubtedly generate substantial quantities of diffuse source TDS which drains currently to the river system and/or seeps into the aquifers below. These may in future have to be located on impermeable clay base materials (Some fortuitously

already are). Alternatively a system of underdrains may in future be required to collect seepage below the wasterock piles.

It can be anticipated that seepage and runoff diversion drains will be required around wasterock piles and the collected water will need to be stored. This water is already recognized as a potentially useful source of additional process water after treatment.

A firm of geotechnical consultants in South Africa that are particularly familiar with the problems and realities of the situation is:

STEFFEN ROBERTSON AND KIRSTEN
Post Office Box 8856
Johannesburg 2000
(011) 834-6061
Dr. Oscar Steffen

The overriding characteristic of the Witwatersrand situation as it affects the water supply is its hugeness. The hugeness of the impact potential and the hugeness of the cost of fixing old or existing waste disposal sites should this be found necessary. To be successful on a long-term basis, the tailings and wasterock must be disposed of in a way that does not require "perpetual" maintenance of each site.

All the measures discussed above would reduce the loss of dissolved salts through seepage. Especially as more water is recycled, TDS and contaminant levels are likely to build up in the solutions, and contaminant will become even more important.

AFFECT OF ABOVE MEASURES

Several results of increased recycle, reduced seepage and salt load buildup in plant solutions can be anticipated.

- Much greater use of lime can be expected to treat effluents and tailings, allowing more water to be recycled. For example, the major Vaal Reefs complex on the far West Rand has achieved zero discharge and consumes 10-12 kg lime per ton tailings slime treated which amounts to a cost of $7.8 million per year or R0.86/t ore treated.

- Galvanic corrosion effects especially in the acid uranium sections of the plant would be enhanced. The high pH in the gold circuit would inhibit corrosion there.

In the uranium plant, corrosion would become a problem everywhere that acid resistant materials have not been used - e.g., service water piping, filters, etc. Increased use of corrosion resistant stainless steels can be anticipated.

- Lining of return water dams and some tailings dams would change the water balance and provide additional quantities of return water available for recycle.

- Effluent streams would have higher concentrations of some dissolved solids and would be unlikely to meet the effluent discharge limits. In this sense the threatened stricter effluent salt content regulations could result in more water being evaporated because it does not meet effluent limits and consequently less water for discharge. The Vaal Reefs trip report in Appendix I shows how this huge mining and milling complex recovers as much water as possible from their tailings for reuse and has achieved zero discharge apparently with an equilibrium salt balance in their recycled water, since salts are precipitated in the tailings material and left in the tailings impoundments.

- It is significant that TDS levels in the Vaal River which flows through the huge Vaal Reefs Exploration and Mining Company Ltd. operating area does not increase from the point of entry to exit from the property. This is an excellent illustration that the effect of a major mining and milling operations on TDS of water in the area can be controlled.

ALTERNATIVE APPROACHES AVAILABLE

The above discussion deals with anticipated effects that would be likely to occur if possible future new interpretations of existing regulations as well as new effluent limits are enforced at the same time as further restrictions on water use. Obviously the mining companies are examining all alternatives on a site specific basis. The following is a discussion of a few of the aspects involved.

Greater use of recycled solutions is likely to result in a build-up of TDS not only in the recycled process water but also in aquifers accessible by seepage.

1) Segregation and Evaporation - Ponds and Linings

One means of reducing overall TDS is by segregating the effluent solutions with highest TDS and other undesirable contaminants for separate disposal or treatment. These could be the excess U-plant raffinate containing 30,000 mg/l TDS. Also possibly the regeneration solutions from boiler feedwater pretreatment plants and boiler blowdown might be segregated. Lined evaporation ponds may be required to dispose of these solutions and others. However, raffinate with its high iron content

seems to be useful at both ERGO and VAAL REEFS for reducing arsenic and cyanide levels in reclaimed water.

One company was found that specializes in lining evaporation ponds with activated bentonite which they claim is more effective, safer and less expensive than plastic linings. To date they have lined over 2 million m^2 of dams including one pond of 160,000 m^3, believed to have been installed to prevent seepage of raffinate from a pond perched alongside the Vaal River in the Klerksdorp area for Vaal Reefs Mining & Exploration Company. The cost of installing an activated bentonite liner at 10Kg/m^2 with a 150 mm (6") thick compacted till cover is around R5.00/m^2 (US$0.30/$ft^2$). More details on the application are available from the vendor:

Skokie, IL 60077
(312) 966-5720

Evaporation of minewater from a new mine in the OFS Goldfields was discussed by BENTEL and JAMES (1983) of Steffen, Robertson and Kirsten. This case must refer either to BEISA or BEATRIX mine of GENCOR LTD. In that part of the country aquifers are very high in chloride levels which would require desalination to make the water usable - an expensive alternative. BENTEL and JAMES (1983) discuss design aspects of evaporation dams which conform to the requirements of the South African Water Act of 1956. The act also requires trenches to collect seepage and prevent its migration to adjacent farmland.

The cost of desalination was found in this instance to be about three times that of evaporation in the unlined ponds which, according to their paper cost only R5000-R10,000 per hectare. If the ponds had to be lined the approximate cost in the USA would be $150,000 per acre for the complete pond. Lining using the Aquasave method is estimated to cost about R50,000/hectare in addition to the basic pond construction cost, i.e., a total of around R60,000/hectare ($13,000/acre).

Based on BENTEL and JAMES (1983) statement that desalination would cost three times evaporation, it would appear then that if the ponds had to be lined in

sensitive locations to protect usable aquifers, then partial desalination at least may become economically attractive especially if the price of water were raised to say R0.50-R1.00/m^3. The point is that desalination in such a scenario is no longer so far out of line cost-wise as to be ruled out.

2) Corrosion and Abrasion Control

One of the most important revelations concerning the impact of water quality on mining costs was made by Alec Mokken, a former consulting metallurgist from Union Corporation Ltd. before it merged into Gencor Ltd. MOKKEN (1964) points out that the cost of pipe, pump and valve replacement in Witwatersrand gold mines is significantly greater per ton of ore mined than the total cost of milling the ore. Much of the replacement costs are the result of corrosion which is directly attributable to water quality effects and abrasion.

His paper was inserted in Chapter 23 on acid mine drainage.

Various types of abrasion and corrosion control measures may be considered. Measures adopted by Rössing Uranium Ltd. in Namibia, South West Africa could be emulated in the uranium plants - e.g.:

- Use of recycle solution for pump gland service. This requires installation of stainless steel pump shafts and seal housings. Possibly this would be an area where the innovative plastics component designer in Virginia OFS could play a role:

  MR. ALAIN LEGER
  Post Office Box 47
  Virginia OFS
  South Africa 9430
  (017) 3-3075/3-2194
  Telex: 8-4770

- Corrosion protection of thickener parts made of stainless steel. Some success has been achieved using polyurethane coatings. Two sources could be evaluated:

ATLAS FOAM (PTY) Ltd.
Post Office Box 2268
Trekker 1547
South Africa
(011) 558-504
Graham Pole

- This two component polyurethane product is also offered by BAYER, LEVERKUSEN, West Germany, and a similar product is offered by Uniroyal in the U.S.A.

- A proprietory polyurethane coating with similar properties is made and installed by:

WEAR RESISTANT MATERIALS (PTY) LTD.
2 Kelsey Place
Asquith NSW 2078
Australia
(02) 476-5655
Telex: Chatswood Public Telex Office,
WRM POL AA 70410

3) Scale Control

Since scale and corrosion are frequently associated with bacteria these may possibly be inhibited through use of appropriate bactericides.

Enhanced scale due to gypsum buildup may be countered through the regular use of scale inhibitors and particularly devices such as Calgon Corporation's dynamic scale monitor for use in selecting the correct reagent and dose.

There are several companies that offer such water treatment products but in South Africa so far only Calgon Corporation offers the dynamic deposit monitor as well as access to the CALGARD computer program for predicting scale and corrosion properties of various solutions.

It is interesting to note that RAND WATER BOARD water cannot be used directly to wash filtercake on drum filters in gold circuits. This is because the bicarbonate in the water results in $CaCO_3$ scale formation in the webbing of the filters and will eventually restrict the hydraulic capacity.

$$HCO_3^- + OH^- + Ca^{++} = H_2O + \underline{CaCO_3}$$

Every so often it is necessary to acid wash the filters to remove scale. An acid corrosion inhibitor is used to prevent attack by the acid of the steel. The corrosion inhibitor is an organic compound which adsorbs onto the steel surface. It was described in the SAIMM Journal, February 1958, pp. 307-342. It is marketed by

REEF CHEMICAL (PTY) LTD.
Boksburg North
South Africa

This is one case where use of barrens or tailings return solution is more suitable for filtercake washing than fresh water, from a scale point of view.

Polypropylene peg scouring of solution lines may be required more frequently as a means of removing scale accretions.

Fungus Control

Another water quality effect that has been found to affect filtration, this time in the acid uranium circuits, is due to fungus growth in the warm solution. It is not known to what extent increased recycling of solutions would affect this phenomenon which can blind the filter media and the wooden webbing behind it. By treating the filter cloth with hot water at 90°C for one hour per week, filter duty of media has been extended from 20 days to over 55 days. Another means of controlling the fungus that could be considered would be through dosing with a fungicide.

4) Water Treatment

Control of dissolved metals build up in recycled solutions may be achieved by treating a slip stream.

One operation observed that when iron and manganese build up in their process solutions, recovery of gold tends to drop.

In order to control levels of dissolved metals including Fe and Mn, an effective process employing lime, air, raffinate, and a mixture of tailings and recycled water is employed very effectively at Vaal Reefs (see Appendix I). The following additional processes might be tested.

- Lime to pH 10.5 and aeration followed by precipitate settling and clarification of solution.

- Lime-soda-alumina desalination can reduce even SO_4 levels as described in Chapters 13 and 51.

- Alkaline chlorination to decompose metal cyanide complexes prior to aeration, flocculation and settling. Alkaline chlorination does not remove iron cyanide complexes however and results in chloride ion buildup.

- SO_2 or roaster gas conditioning of tailings or recycle solution at pH maintained near 9 to decompose metal cyanide complexes including iron cyanides and precipitating metals.

- Greensand filtration may aid in polishing Fe and Mn from effluents after precipitation of bulk metals. Generally greensand filtration is not economic for removal of more than about 10 ppm Fe and Mn, however.

Further solution treatments that may be considered include:

- IX removal of Fe and Mn.

- Lime soda softening to remove calcium.

- Aeration at pH below 7 to remove HCO_3^- which otherwise results in scaling on activated carbon when pH is raised.

- A new improved variation of the theme of High Density Sludge precipitation of metals from Witwatersrand effluents is under development which may remove CN^- as well as metals.

5) Desalination Alternative

The new slurry seeded R. O. and Evaporation processes offer particular promise for scaling solutions containing Ca^{2+} and $SO_4^=$.

Advantage of Desalination: Reduces TDS including species which lime - settling and clarification cannot remove, for example, chloride and sodium. Several alternatives are available. A major advantage of desalination is that it recovers good quality water.

Disadvantage of Desalination: High capital and operating costs. Desalination processes are discussed in Chapters 15-19. However, operating cost estimates of

PIPE CLEANERS

The PIPE CLEANING SYSTEM

Step 1: To determine smallest diameter of scale build up within the pipe.

Take a foam swab and pump it through the line. The foam swab will wear down to the smallest diameter inside the pipe. By measuring this diameter the size of the 1st studded Polly-Pig can be determined.

Step 2: Removal of Scale Build-up

Having determined the smallest diameter of the scale build-up within the pipe insert the studded Polly-Pig of same diameter and pump through the line. The operation is repeated using studded Polly-Pigs 12 mm larger in size, until the original diameter of the pipe is reached. The pipe should now be free of scale.

Step 3: Brush and polish for final cleaning

Once all the hard scale has been removed a Javelina Polly-Pig is pumped through the pipe line. This removes final traces of scale and cleans pipe to a smooth finish.

Sizes available from 50mm to 1500mm (in 12mm increases per size)

R. J. SPARGO Ltd.

P.O. Box 3793, Alrode 1451
Tel. (011) 864-2744 Telex 4-20365

$0.50-R0.60/m^3, including capital amortization, is not that much out of line with lime treatment of effluents in parts of Canada (C$0.60-C$1.80), or Vaal Reefs bulk neutralization process requiring R0.80/t ore in lime for water treatment.

6) In most cases with Witwatersrand-type climates, if alternate sources of water can be found, it will be cheaper to dispose of high TDS effluents by evaporation than by trying to treat the solutions, especially if desalination is involved.

Use of mine drainage water pumped from underground causes a cone of depression around the tapping point and should cause migration to the tapping point of contaminants in the aquifer. This offers a possible way to clean up contaminated aquifers.

7) Significant quantities of treated sewage water are available from sewage plants at the mine hostels and local municipalities.

- Treated sewage effluent water can be used without problems in gold recovery operations when the Merrill-Crowe process is used. Its effect on CIP performance needs to be studied.

- It is believed, without firm plant scale data, that reclaimed sewage water used in acid pH flotation of pyrite-gold from tailings results in a drop in recovery of gold, pyrite, and uranium. These observations have been indicated at President Brand Gold Mining Company where from time to time some reclaimed sewage water is said to have got into the process solution.

- Anglovaal Research Laboratories tested reclaimed sewage water from two types of sewage plants for high pH flotation of gold and pyrite. In one case the results were as good or better than when fresh water is used; in the second case there was a definite interference.

- The first flotation test case (where no interference was found) used reclaimed sewage water from the new Stilfontein sewage treatment plant which uses an activated sludge process. The second case (where there was interference) used water from the older sewage treatment plant which uses biofiltration. These tests indicate the possible merits of activated sludge sewage treatment where the product water is to used for flotation.

- Anglo American Corporation has observed, again only quantitatively, that if reclaimed sewage water is used in the Peabody scrubbers to clean and cool SO_2 gas after roasting, then after this step it becomes usable in flotation without interference in the flotation process.

- President Brand Gold Mining Co. used a reclaimed sewage water component in CIP gold recovery from leached calcines. It was found that CIP recovery was adversely affected, although there were other contributory factors.

- Rohm and Haas has developed an experimental resin for removal of humic acids from solutions and pulp. This product is not commercially available.

- The discussion on water quality effects on flotation in Chapter 54 mentions several potentially useful observations on the use and impact of sewage water on flotation recoveries.

It was mentioned that either the R & H experimental polymeric coagulant XE-392 or their range of Ambersorb carbonaceous adsorbents might be useful for this application. The price of these products is however relatively high at $11-14/lb. More information can be obtained from:

ROHM AND HAAS COMPANY
Independence Mall West
Philadelphia, PA 19105

Carl A. Panza

8) The possibility of polyelectrolyte or polyacrylate flocculants and other long chain organic compounds present in treated sewage water having an adverse effect on carbon adsorption of gold requires further investigation. One way to consider would be biological degradation - another would be through the use of clays to scavenge these materials and settle them. More information about new applications of this sort for activated bentonite can be obtained from:

MR. JOHN DENT
Drillchem (Pty) Ltd.
Post Office Box 78642
Sandton 2146
(011) 783-4456

9) Stearic acid, even in trace amounts, have an adverse effect on molybdenite flotation. Possibly, stearates (soap) in sewage effluents are one possible cause of interference in flotation efficiency.

10) Witwatersrand gold mines are very deep and hot. All water pumped underground is first disinfected by chlorination to breakpoint. Mineworkers are accustomed to drinking whatever water they can find in the stopes and since undoubtedly a considerable amount of coliform bacteria is generated underground, thorough disinfection is considered essential.

One mining house, Gold Fields of South Africa Ltd., has been seeking ways to use reclaimed sewage water as cooling water underground. However, since the water contains relatively high ammonia levels the problem of excessive chlorine consumption to achieve breakpoint each 1 lb NH_3 consumes 10-15 ppm Cl_2. If less chlorine is used, chloramines are formed. These chloramines may be toxic or may themselves be adequate as a means of disinfecting minewater. This is a topic for ongoing research. At some Gold Fields operations (e.g., Kloff), a sewage treatment process yielding an effluent with max. 0.5 ppm NH_3 has been installed.

Calgon Corporation proposes that the use of chlorine dioxide would be more economical for disinfection of reclaimed sewage water and also for minewater containing coliform bacteria. More information can be obtained form FLOCCOTAN (PTY) LTD. or CALGON CORP., whose addresses were listed above.

11) Use of reclaim sewage water containing ammonia and chlorides in underground refrigeration and also in the above ground compressor cooling stations introduced a problem in that copper-nickel heat exchanger coils were corroded. After investigating the problem with the help of the CSIR, the problem was solved by appropriate materials selection.

CALGON pointed out that copper corrosion by ammonia attack of refrigeration tubes could be inhibited by use of a calgon product called TOLYTRIAZOL. This reagent is also not destroyed by chlorination.

12) Ongoing research in South Africa at the National Institute for Water Research, Pretoria is investigating the use of a clay known as Clinoptilolite to remove ammonia from solution. Tests to date indicate that NH_3 can be reduced from 20 ppm to below 1 ppm without much difficulty. Clinoptilolite is used for this purpose in some U.S.A. municipal water treatment plants. See Chapter 22 on ammonia removal.

ERPM acid minewater is currently neutralized with lime and settled to remove the "easier" metals using the HDS process.

Several publications have described the Bethlehem Steel Company High Density Sludge (HDS) Process. Although installed and in use in a variety of forms at several companies, the best source of information is probably still Bethlehem Steel Co. who offer the technology and knowhow for sale together with an innovative way to make the sludge disposable under the new Hazardous Waste Regulations in the USA.

BETHLEHEM INTERNATIONAL ENGINEERING CO.
Bethlehem, PA 18016
(215) 694-7763
Telex: 847417 Mesbeth
Jim Forand, Vice President
Stewart Hermann

The process has also been described by among others VAN STADEN (1979); KOSTENBADER & HAINES (1970); HERMAN (?); HERMAN & KORB (?); BIEC Technology, Issue 4, July 1982; and TEMMEL (1971).

14) Examining the water quality parameters listed below for a typical Witwatersrand mine-mill complex it is clear that when manganese is used as an oxidant for uranium leaching, then manganese levels can be high in the tailings and in U-plant raffinate. It may be necessary to remove manganese from effluent streams. Manganese has been a problem in the past in the municipal water supply of at least two metropolitan areas downstream from gold and uranium extraction plants.

In order to precipitate manganese by aeration a very high pH is generally required. Surface effects and bacteria also play a role in precipitating manganese according to HEM (1970). Sulfide addition will quantitatively remove manganese even in alkaline solutions as described by LARSEN & ROSS (1976).

The CSIR in South Africa developed a process whereby divalent manganese is precipitated by adsorption into MnO_2 coated sand. Details of this process were considered confidential early in 1984, but now more information may be available. The process is very pH dependent with faster and more complete removal above pH 9. Addition of chlorine up to 50 mg Cl_2/l has a marked improvement on manganese removal which can be almost quantitative even at pH 7.0 after ten minutes. The combination of pH increase and Cl_2 addition makes it possible to accelerate

removal of Mn^{+2} to below 1 ppm. However addition of minute quantities of MnO_4^- has a dramatic effect on Mn^{+2} removal to extremely low levels.

AMAX Inc. is believed to have experience with innovative practical applications of some manganese/chlorine reactions, but these are company confidential.

Manganese removal has been extensively examined by numerous authors and is discussed in Chapter 43 of this report. However, the tailings/raffinate treatment with lime described for Vaal Reefs (Appendix I) shows that manganese can be kept below 1 ppm in tailings return water. However, lime costs are high to achieve this.

CHOICE OF PROCESS CIRCUITS

South African gold and uranium recovery plants have historically used a highly efficient drum filtration for solid-liquid separation ahead of gold and uranium recovery. In the late 1970's belt filtration was introduced at some South African uranium plants, notably Vaal Reefs East, Harmony, Randfontein Estates and the Chemwest Ltd. operation at Stilfontein. Belt filtration was also used at Randfontein Estates for gold recovery but it has not become widely accepted for this application. The South African industry preferred to use filtration as a means of solid-liquid separation because the Witwatersrand ore filters quite well despite its fine grind, especially at the high pH levels used in gold plants. At Vaal Reefs South and other locations, large CCD thickeners were installed for uranium recovery with some success although more dilute solutions result.

There are several process sequence arrangements to choose from in recovering gold and uranium from Witwatersrand ores and tailings. These will be reexamined from the point of view of water consumption requirements and subsequent effluent treatment costs. The variations on this theme are too many to be evaluated here. Some general ideas are mentioned as to where future innovations may be found - from a water management point of view.

1) Belt filtration provides a means of applying multiple counter-current washing steps of a leached ore, as well as the potential for dry tailings disposal. The use of belt filtration on the Witwatersrand has to date been limited to uranium circuits, except for the Cooke Plant of Randfontein Estates where it is used for gold recovery. Washing performance in the uranium plants has proven not nearly as good as originally expected with reports of 2-4% soluble losses apparently being typical. Randfontein Estates claims 0.5% soluble gold loss at Cooke Plant. It must be pointed out, however, that the uranium plant belt filter installations do not apply the filters as designed either - they are not using multiple counter-current washes because of operating difficulties in doing so.

New innovative approaches to solution distribution in filter cakes may, if combined with appropriate operator training and revised maintenance approaches, make belt filtration attractive even to the extent of being appropriate for gold filtration. One such idea with merit involves the addition of wood pulp fiber as a filter aid to the pulp ahead of filtration. This has not yet been proven, and probably would be a bad idea if the tailings were to be repulped and leached as feed to a CIP plant.

The main attraction of belt filtration is that it can theoretically wash a pulp to yield less than 1.0 tons of pregnant solution per ton solids. Belt filtration has been selected for its water efficiency both inside and outside South Africa, but even in France, where the most sophisticated use of belt filtration has been made, typical installations yield 2-2.2 m^3 pregnant solution per ton ore. Pioneer Nuclear Corp. in the late 1970s designed and tested a two-stage counter current leach and washing circuit for uranium leach pulp to be installed in Colorado where water in very limited supply. CCD circuits require typically 3.0-3.5 tons water per ton solids and expose large areas for evaporation losses.

At this point, however, conventional drum filtration is still a safer bet than belt filtration as far as soluble loss is concerned, yet requires much less water than CCD and yields solutions with lower suspended solids than either CCD or belt filters. Drum filters are, however, more expensive to install.

2) Carbon-in-pulp has become accepted in South Africa as a "conventional" process. The advantage of the process is that better gold recoveries are achieved and capital costs are lower. These factors are even more noticeable in calcine leaching. One major disadvantage is that the CIP process does not offer the opportunity to recycle cyanide-bearing barren solution back to leaching and filter wash, except after decantation in the tailings pond. Even then, cyanide value recovery would be poor.

Overall water requirements for CIP and drum filtration are about equal assuming 45% solids is used in the CIP circuits. However, CIP tailings go to the dam before solution can be decanted for recycle by which time much of the cyanide values will be lost to natural degradation, especially if the tailings are commingled with other effluents in the neutralization plant.

It may be possible to modify tailings disposal concepts to reclaim more cyanide values from CIP tailings. There are options that can be considered on a site specific basis.

3) In recycling solutions, TDS and metal ions are likely to build up unless removed by treatment. CIP adsorption of gold is generally more tolerant in this respect than zinc precipitation, and offers some advantages. FLEMING (1982) of MINTEK claims that resin in pulp offers additional advantages and these are being evaluated in South Africa.

4) For efficient carbon elution, water quality is critical and fresh water, possibly even demineralized water should be used for this step.

5) There is an increased interest in pressure oxidation of some Witwatersrand ores as a means of liberating locked up gold and improving both gold and uranium recovery. This would replace flotation, roasting, and calcine leaching for gold and leaching the flotation tailings separately for gold and uranium. It is too soon to tell what the impact will be on overall water consumption or water treatment needs. Tailings from this process being already oxidized will be inert and less likely to generate acid and TDS.

6) Several wasterock piles on the Witwatersrand are subject to study as potential heap leaching targets. In order to leach wasterock it is possible that the older piles will be re-sorted using ore sorters and the discard from these may be further crushed and stacked for leaching. This would present an opportunity to place the material on impermeable pads which could serve as a means of collecting solutions draining through the heaps long after heap leaching ceases. This concept is still in its infancy and is experimental. It will not replace the need for crushing and grinding of ore however but represents possible incremental recovery.

7) Experimental work on in-situ leaching of sand tailing dumps has not yet been published, and it is too early to evaluate water management needs and techniques for this process approach.

8) Heap leaching of reclaimed sand tailings is practiced at one site on the Witwatersrand but is unlikely, despite its apparent success, find general application. At Sevcorp's operation, tailings are disposed of by selling the sand to contractors.

9) There is a major expansion in re-processing of gold mill tailings on the Witwatersrand. Such projects include:

ERGO	1,500,000 tpm	U, Au, and S
Sallies-Daggafontein	1,000,000 tpm	U, Au, and S
RM3	420,000 tpm	
Chemwes Ltd.	270,000 tpm	U
Severin Resources	Small	Au and Sand

Various processing arrangements are in use. One major impact these will have on water impact is that the tailings can be disposed of in a more modern fashion which can reduce the impact of the tailings on ground and surface water. Pyrite values are recovered by flotation in several cases which reduces the acid generating capacity of these tailings when disposed of in their final impoundments.

TYPICAL WITWATERSRAND GOLD-URANIUM MINE-MILL WATER REQUIREMENTS

The water chemistry and balance of a hypothetical Witwatersrand gold and uranium mine situated over a dolomitic aquifer is shown below.

If tailings reclaim solution is to be recycled to the plant, then it is logical to expect TDS in the solution to increase. TDS in dolomitic water drawn from underground aquifers may increase due to seepage from the surface.

It is noted that a bulk neutralization tank receives water and tailings from all over the plant. After neutralization it is pumped to the tailings pond, and then reclaimed for judicious use in the metallurgical plants.

1) Repulped tailings from U-Plant filters.
2) Excess raffinate from barrens storage tank.
3) U-Plant spillage.
4) Precipitate hosedown water.
5) Boiler blowdown via lined ponds.
6) Boiler feedwater softening waste via lined ponds.

This represents a typical present case based on blended fragments of information for several operations. Many of the Witwatersrand mine-mill complexes are net users of water and do not discharge any point source effluents. What the situation would be if seepage from tailings dams and reclaim water ponds etc. were to be eliminated is not yet quantified.

RAND MINES MILLING AND MINING CO. LTD.

Rand Mines Milling and Mining Company Ltd. (RM3) recovers gold and uranium from large gold mine tailings on the outskirts of the city of Johannesburg. RM3 is the subject of a trip report, but it is of interest here because of possible water quality effects on metallurgical recovery in this type of metallurgical plant. Comments made in this respect are hypothetical to illustrate some of the factors that need to be considered in designing such plants.

The basic flowsheet employs repulping of the tailings feed and a sand-slime split, with slimes going directly to cyanidation and CIP recovery. Sand is floated to yield a concentrate containing enriched gold and pyrite values. The concentrate is ground to 95% minus 200 mesh, cyanided, gold recovered in a separate CIP circuit and then floated again to make a 40% sulfide concentrate for shipment to roasting plants to make sulfuric acid.

The sand flotation tails are milled to 50% minus 200 mesh, and added to the slimes fraction for cyanidation and gold recovery by CIP. Capacity of the operation is 375,000 t/mo sand and 45,000 t/mo slimes.

Recycled water, runoff, and water from a local creek meet almost the entire needs of the operation. 45,000 m^3/mo recycled tailings dam water is used for the repulping of slimes dam material using monitor jets. 656,000 m^3/mo recycle and surface water with some Rand Water Board water are used to repulp the sand tailings.

The CIP plant performance has not been quite as expected on the basis of pilot plant tests. RM3 believe that this was due to two main factors:

1) Flotation reagents caused initial interferences with carbon adsorption of gold. This was overcome by using a different frother known as TEB supplied by NCP.

2) Water from the local creek that was used proved to be contaminated with organics believed to have originated from upstream industry.

If the operation is examined from a water management point of view, it is found that water is recycled in two main loops. In the first, sulfide-bearing tailings in varying degrees of oxidation are repulped with recycle water primarily from the tailings dam, and from so called industrial water tanks which contain recycle and stream water which has been lime precipitated and settled.

It is believed that this recirculation of water that has been in contact with oxidizing tailings as well as the flotation concentrate may build up levels of thiocyanate, soluble

RM3 FLOWSHEET

RM3 WATER RETICULATION

sulfide, sulfate, ferrous and ferric ions and cyano complexes and possibly some humic acids and degradation products from the flotation reagents. One might speculate that thorough aeration of this recycled water at a high pH to oxidize and precipitate ferrous iron, or additional water treatment steps--e.g., biological--could have a positive influence on metallurgical recoveries.

West Australia

West Australia is arid but no more so than much of Nevada as far as climate is concerned. What sets it apart is that good quality groundwater does not appear to be available in areas such as Kalgoorlie - Norseman, which has been Australia's major gold mining center since before the turn of the century.

Significant development of the gold deposits in this area had to wait until the Goldfields Water Scheme was installed to bring water from Mundaring Weir near Perth, a distance of over 300 miles.

Present day mining and metallurgical operations rely on water from the following sources in addition to that piped in by the Goldfields Water Scheme:

Saline Groundwater (up to 15% TDS)
Recovered Process Water
Harvested Storm Water
Recovered Community Effluent

The Western Australian gold deposits are relatively small compared with South African operations - generally 500-2000 tpd on the Golden Mile, 1600 tpd at Western Mining's operation at Kambalda, 1000 tpd at Whim Creek's operation Meekatharra, and numerous small operations scattered throughout Western Australia.

Many of the ores are associated with sulfides and base metals and ore types are by no means uniform from one deposit to another - on the contrary, mineralogy of the ores is highly variable. Several of the ores require roasting to make them amenable to cyanidation. Calcines are washed before leaching.

Water at around A$1.00/m^3 is expensive and not always of the best quality. Water is recovered for recycle to the greatest extent practicable. However with further growth in the mining industry in this region available water supplies may become hard pressed to meet demand and further conservation and recycle may be needed.

Western Australian gold mines were visited during 1982, but it was not possible to visit them again to determine operating parameters with respect to water. Questionnaires have

been sent to each operator enquiring as to their water management practices, and responses have been summarized in Chapter 3.

During September and October 1984 Broken Hill Proprietory Ltd. was retained to undertake a survey of the Western Australian water needs and at what price water pumped from the Mundaring Weir near Perth would be economically substituted by alternative sources of lesser quality. Some additional information might be available from:

BROKEN HILL PROPRIETORY CO. LTD..
GPO Box 86A
Victoria 3001
Australia
60-0701
Hilton Duke

Although the study is probably client confidential BHP would undoubtably be able to provide some general insight into the Western Australian approaches to water management.

Some of the water conservation measures observed in Western Australia are as follows:

1. Placer Mining Without Water

Australia is known for very large gold nuggets in some of its desert placer country. One innovative way of recovering these has been by mounting multiple metal detectors on a wheel mounted frame that is driven across the desert. Any signals are investigated to find nuggets. It is questionable whether this innovative technique will account for more than a very limited gold production in extremely site specific instances. It, however, consumes no water - only gasoline and beer.

2. Evaluation of Placer Gold Deposits where Water is not Available

When a major gold deposit is found then water of some or other quality may be found at some distance and piped in. During the exploration and evaluation phase however, large bulk samples must be tested and the options are to truck ore to the nearest water or to truck water to a test site adjacent to the deposit. In Western Australia this could mean hauling ore or water thirty miles or more. Even though these units achieve a lower recovery of say 70% compared to jigs for which 90% recovery is claimed by some, results from these test units can be calibrated accordingly. If a deposit is proven to be economically viable, then part of the capital investment may be allocated to bringing in good quality water

3. Flotation and Roasting

Several Western Australian gold ores require flotation and roasting before the gold is amenable to cyanidation. Examples of such plants are:

1) Kalgoorlie Mining Associates, Fimiston
2) North Kalgoorlie Mines Ltd., Fimiston
3) CSR Paringa Mining Co. (Pty) Ltd., Kalgoorlie
4) Lancefield Gold Project, Windarra
5) Several additional deposits under evaluation in Western Australia

Cyanide depresses pyrite flotation and must therefore not be present in flotation plant water. This must be taken into account when recycling water in such operations which employ flotation, roasting and leaching.

Fortunately Western Australia has a very hot climate especially in summmer and solutions need not be aged very long for natural degradation to decompose cyanide. However, evaporative losses are also likely to be very high. Also the extent to which ferro and ferricyanides are removed in the tailings pond is not known, nor is the degree to which these stable cyanide complexes interfere with flotation of pyrite and gold.

After roasting, calcines are washed in water to remove soluble metal salts e.g., Fe, Cu, Ni, which otherwise would consume cyanide and interfere with subsequent

METALLURGICAL FLOW DIAGRAM

processing steps. It is not known how the wash solutions are disposed of or recycled at the existing operations. The KMA flowsheet does however show the washwater as being disposed of rather than recycled.

Alternative 1: Reclaim Usable Water Using HDS from Barren Bleed and Calcine Washwater

Calcine washwater contains metals in acidic solution as hydrated cations in the absence of cyanide. Barren bleed contains base metals and iron in the form of cyanide complexes.

Randol International Ltd. suggests four possible ways in which usable water can be reclaimed from these wash solutions.

- Precipitation of metals from the calcine wash solution with lime using HDS, settling and clarification.

- Blended of wash solution with barren bleed containing cyanide complexed metals for HDS cyanide removal, metal precipitation, HDS, settling, and recovery of water.

- Use of the Prussian Blue precipitation with cross-flow filtration to remove metals as cyanide and hydroxide precipitates, allowing decant solutions to be recycled.

- FeS addition should probably be avoided because of undesirable affects of sulfide ions on subsequent cyanidation steps. HDS is recommended for the following reasons:

  1. HDS results in efficient lime use;
  2. HDS results in a high density sludge for easy disposal; and
  3. HDS will remove iron, heavy metals and cyanide from the combined flow with less reagent addition than required to treat both solutions separately.

  Note: The above is a purely conceptual application of HDS and requires proving on laboratory, pilot and commercial scale.

Calcine tailings after cyanidation should be stockpiled in a separate disposal site for possible future treatment. This would also keep cyanide out of the flotation tailings from which decant water is recycled back to the front of the process.

More information on the HDS process particularly on details as to how it can be applied for cyanide removal (patent applied for) can be obtained from the developers of the process. Bethlehem Steel application of HDS for cyanide removal should be regarded as confidential until their patent is issued.

BIEC TECHNOLOG
ISSUE 4 • JULY 1982

High-density sludge process– an improved technology for treating acidic metal-bearing wastewaters

Many wastewaters from steel plant and mining operations have traditionally been difficult to treat effectively prior to approved discharge into public waters. The reason: conventional neutralization processes that treat acidic metal-bearing wastewaters produce very dilute sludges and are not efficient in precipitating mixtures of dissolved heavy metals. Bethlehem International Engineering Corporation is authorized to license a high-density sludge process that does this job better and more economically than conventional processes.

Also applicable to the treatment of acid mine drainage, the process may reduce costs to build and operate a treatment facility. This economy results from: (1) a substantially higher-density sludge, (2) improved slurry filterability; (3) improved reduction of metal concentrations, and (4), in some cases, the smaller size of the clarifier/thickener required.

The process is in operation at three Bethlehem Steel Corporation plants, five Bethlehem Mines Corporation bituminous coal mines, and a South African gold mine. A new facility for a Bethlehem Mines Corporation anthracite coal mine is under construction. (See Table, Figure 3, on reverse side of this sheet.)

This technology is now available for licensing from Bethlehem International Engineering Corporation.

Alternative Water Sources

1. High TDS Saline Water

If saline water is used in flotation, we have no experience in the extra costs involved or metallurgical effects in this environment.

Note: Chuquiquamata Div. of Codelco is believed to use high TDS water for copper flotation with success.

2. Reclaimed Sewage Water

Has been tested in South Africa and found to have resulted in varying gold and pyrite recovery losses depending on the quality of the treated sewage effluent. Qualitative observations found that if this water is used as a coolant inside the Peabody scrubbers in the roaster gas stream, it becomes usable. Tests have also shown that activated sludge sewage effluent treatment may render it usable with no detrimental effects on flotation recoveries.

3. Harvested Storm Water

No problems anticipated as long as there is enough of it and suspended solids are removed.

Alternative 2: Use of Roaster Gas

This alternative uses calcine washwater and barren bleed from cyanidation to supplement process water in the grinding of the incoming ore. Cyanide and metal values interfere with flotation and must be removed. SO_2-Air and lime can be used to pretreat the mixed solution to destroy cyanide and precipitate dissolved metals. Alternatively the pulp flotation feed can potentially be conditioned with SO_2 at pH 8-9 prior to flotation as a means of destroying cyanide and precipitating base metals and soluble iron before the flotation step.

Note 1) After multiple recycling of flotation tailings reclaim solution, these may develop characteristics that are deleterious to flotation and require additional treatment steps.

Note 2) Calcine leach and CIP tails should be stockpiled separately from flotation tailings to keep CN out of the flotation tailings reclaim water.

Note 3) Additional water could be recovered by dewatering flotation tailings which would then be disposed of as "dry" tailings. Economics of this step depends on the price of water.

Note 4) INCO Ltd. market the patented SO_2 process for cyanide removal.

Information on the use of SO_2 for cyanide destruction and metal removal from recycle solutions can be obtained from the world experts in this field:

Mr. Eric Devuyst

3. Alternative Metallurgical Processes

An alternative patented process has been described by DUNN (1983) which requires no grinding and virtually no water. Roasting of finely crushed ore in a shaft furnace would require very little energy. It is noted that this process is still in the

developmental stage and has yet to be proven on pilot and commercial scale. High water prices or lack of water availability may give this process some added appeal. It is certainly a simple concept with potential overall cost and recovery improvements.

4. Flotation and Leaching of Concentrate

Certain sulfide ores in Western Australia do not leach well directly. However, a flotation concentrate from these ores can be reground and leached under more aggressive conditions with adequate recoveries avoiding the need for roasting. One such ore was the Mt. Charlotte ore of the Kalgoorlie area company now known as Kalgoorlie Mining Associates in which Homestake Mining Company of the USA has an interest. A flowsheet of the process used for this ore is provided below. It shows flotation concentrate and tailings thickener overflow solutions were both returned to the grinding circuit.

Flowsheet of Croys treatment plant of Kalgoorlie Mining Associates.

This flowsheet allows a regrind of the concentrate, aeration and cyanidation using more concentrated reagents than could be economically justified for the whole ore.

The flowsheet of the Oroya treatment plant shown above is based on water availability at a reasonable cost. In it there is a significant bleed of water to the tailings dam with leached concentrate and thickened flotation tailings. No reclaim recovery of this water beyond the thickener o/f is shown. After aging in the tailings pond, decant solution from the tailings pond may be used directly in the front end of the process if all free cyanide has been lost by natural degradation or alternatively some or other cyanide removal process may be necessary:

- Alkaline chlorination.
- Bethlehem Steel HDS process with added iron.
- SO_2 cyanide destruction in presence of copper.
- Bacterial cyanide removal.
- H_2O_2/Cu cyanide decomposition.
- $FeS/FeSO_4$ addition followed by aeration.

Alternative Sources of Water

High TDS water may be used possibly without detriment depending on its composition.

Sewage reclaim water may possibly be used, but only after appropriate activated sludge treatment or by treating it with roaster gas, subject to confirmatory testwork.

If the price of water is high enough, the flotation tailings water could be partially recovered by installing a dewatering step e.g., filtration to dewater the tailings for dry tailings disposal using a belt press.

Consolidated Gold Fields Ltd. in considering a spectrum of metallurgical processes for the Mahd adh Dhahab ore deposit in Saudi Arabia in a hot desert climate have elected to recycle solutions as follows from a combined flotation-leach-CIP circuit, albeit leaching the flotation tailings rather than the concentrate:

1) Dewatering Flotation tailings, recycling water to grind and flotation.

2) Dewatering CIP tailings by filtration and recycling cyanide-bearing barren solution to repulp flotation tailing prior to leaching.

3) Discard "dry" tailings as a filtercake.

Such an arrangement has been calculated to save adequate cyanide in the recycle to justify the capital and operating costs of the barren solution recycle.

Water consumption in the circuit is found to be reduced to one third of that for a plant in which water would not be recycled according to LEWIS (1984).

FLOTATION AND CYANIDATION OF TAILINGS

An example of this flow sheet is that proposed for the Lancefield Gold Project of Western Mining Corporation, and Shell Company of Australia at Laverton, WA. In this case flotation removes most of the gold plus cyanicides, pyrrhotite, pyrite and arsenopyrite which must be roasted before leaching, and a flotation tailing with some gold that justifies leaching.

The cyanide consumers and oxygen consuming species in the flotation tailings are high enough to require high cyanide and lime levels during leaching ahead of CIP. Unless such ores are thoroughly aerated difficulty can be experienced with carbon adsorption and elution.

Calcine from the roaster will be quenched in water which will be recycled via a thickener. About 80% of the washwater will be recycled and 20% bled to keep dissolved metal levels within manageable limits ahead of cyanidation. Temperature in the quench tank is found to be critical - optimum is 60°C. Should temperatures rise to 80°C, gypsum scale formation is serious.

The 20% calcine wash solution bleed could, if economics dictated, be recovered and treated as described in earlier cases.

CIP tails could be dewatered for recovery of cyanide values and water depending on the prevailing cost of water and cyanide and levels of other interfering metal complexes.

A description of the development testwork by LEWIS (1984) on the Mahd adh Dhahab deposit in Saudi Arabia offers interesting insight into cost effective measures for this type of processing arrangement at a location that is both hot and dependent on expensive water.

EFFECT OF CYANIDE SOLUBLE METALS IN ORE

Other factors that can prove important in water management for such flowsheets are the presence of cyanide-soluble copper, nickel and also iron in the flotation tails that leach during cyanidation.

Due to solution recycle, copper levels may build up eventually to levels at which problems are experienced with zinc precipitation by Merrill-Crowe, or copper and nickel can reach

levels that depress gold adsorption on carbon if CIP is used. In some cases these metals may be present at levels that cause problems even when solutions are not recycled.

SCERESINI (1982) showed that 60 ppm Ni in the leach solution from Western Mining Corporation's Kambalda gold ore which contains 0.15-0.25% nickel of which 10% leaches in cyanide, resulting in about 6000 ppm nickel adsorption onto carbon. To reduce the depressing effect of nickel on gold loading additional cyanide is added to the circuit which also reduced the level of copper that adsorbs onto the carbon in the CIP step. LAXEN (1982) however showed that additions of nickel to over 100 ppm did not have a serious effect on carbon adsorption of gold during experiments performed at Gencor Ltd.'s Grootvlei Gold Mine in South Africa.

Nevertheless, careful recycling of solutions could result in nickel level buildup which would have to be treated every so often if they became a problem. More information may be available from:

EFFECT OF PHRRHOTITE

Work at Homestake Mining Company at Lead, SD showed that pyrrhotite must be completely oxidized by preaeration of the pulp before leaching to avoid excessive cyanide consumption and problems in the CIP adsorption/desorption circuit. SALISBURY (1982) point out that when the CIP circuit was started up at Lead, South Dakota, before adequate aeration capacity was installed, gold adsorbed on the carbon partly in the metallic form and was very difficult to elute.

EFFECT OF TEMPERATURE ON CYANIDE CONSUMPTION

HALBE et al. (1979) showed that cyanide consumption at Homestake goes up in summmer which they found was due to the formation of thiocyanate by reaction with soluble sulfides such as pyrrhotite. The rate of this reaction was found to increase sharply above 10° C. Since tailings pond water at 20° C in summer is recycled to the process a greatly increased cyanide consumption was observed compared with an earlier system in which

fresh process water at 4° C was added to the system. Spray cooling was practiced in 1978 with some success and the spray cooling was to be expanded in 1979.

Clearly, one way to reduce cyanide consumption and thiocyanate levels in tails is to leach pulps that generate CNS at a reduced temperature where possible.

If water is to be conserved due to its cost then spray cooling is unlikely to be an adequate answer in the searing Western Australian summers.

EFFECT OF TEMPERATURE ON CARBON ADSORPTION

Gold and silver adsorption on activated carbon is improved at lower temperatures. Consequently recycling of solution to tailings and/or the use of black painted steel pipes to transfer pulps and/or solutions in the plant should be avoided where these are exposed to the summer sun.

VAT LEACHING

Three vat leaching companies were visited in Western Australia. These were:

Grants' Patch Partners, Kalgoorlie
Horseshoe Lights Project, Contech (Pty) Ltd., Perth
Elaura Enterprises (Pty) Ltd., outside Perth

Grants' Patch Partners operates numerous small vat leaching operations treating old dumps scattered around the Kalgoorlie district and employing portable carbon canisters to adsorb gold. These are then transported to Kalgoorlie where the carbon is eluted at a central elution plant.

Water for their operations is usually accessible around or in the old mine workings where the tailings are located, frequently in the flooded shafts of old mines.

Water quality is often a problem. Grants' Patch Partners have used water with up to 1.3% TDS but this was considered close to their upper limit.

There are tailings piles where the only available water contains 20,000 ppm tds which is not usable. In such cases water treatment processes might make the water usable depending on the overall economics of the situation. To date no such water treatment systems have been installed either because the economics of the situation do not justify such installations or because Grants' Patch Partners experience in water treatment is limited.

pH VERSUS CaO ADDITION
BUFFERED MINEWATER

Alunite and gibbsite frequently occur in West Australian gold ores and are found in the tailings. In one case 15% of the ore was gibbsite, which is a hydrated aluminium oxide. The gibbsite buffers the minewater available from the area at pH 6-7 and this water may require up to 10 Kg lime per ton to bring the pH up to the working level of pH 9 or 10.

Based on other evidence in similar instances for water drawn from flooded mine workings, at least a part of the extra lime consumption may be due to high H_2CO_3 in the water. This phenomenon is believed to contribute toward severe carbon scaling in carbon columns and CIP when the pH is increased in the presence of calcium.

One possible way to reduce lime consumption in such cases was demonstrated at the Panther Valley Division of Bethlehem Steel Company where air is blown through the mine drainage water to remove excess CO_2 before lime is added. More information on the phenomenon is available from:

Chief Metallurgist

The importance of removing bicarbonate ions and H_2CO_3 from solutions before addition of lime is grossly underrated in operations. Not only will scale effects be reduced and lime consumption be more economical, but the amount of precipitate that is generated will be reduced too. This factor is particularly significant when a thickener or clarifier is installed as the extra solids generated may even impair the thickener performance due to overloading.

HEAP LEACHING

The only heap leaching visited by Randol International Ltd. in Western Australia was that of Whim Creek Consolidated NL at Meekatharra.

This 300,000 tpa operation combines heap leaching of coarse material with agitation leaching of fines after grinding, followed by CIP.

Whim Creek gets its water from flooded underground mine workings. No information was available on water quality.

It was stated that despite relative costs of \$280/t for Na_2CO_3 compared with \$80/t for lime, soda ash is used for pH control in the leach circuit. The reasons given for this were:

1) A lower cyanide consumption when soda ash is used.

2) Less scaling effects when soda ash is used.

3) Although more expensive than lime, less pounds of soda ash are required for the same rise in pH.

It is not possible to comment on water management based on the information available. Certainly the reasons for Na_2CO_3 preference over $CaCO_3$ invite further investigation. It would be of interest to know what the HCO_3^- level in the raw water is and whether aeration of this water would help reduce scaling when lime is used for pH control.

Although solutions are recycled many times at Whim Creek, no serious scaling problems on the carbon are recalled, but this should be confirmed.

AUSTRALIS MINING N.L.

Use of High Salinity Water in CIP Operations

WEBB (1982) described the Australis Mining Cip Plant at Norseman, Western Australia which was operated at 400 tpd ore throughput containing 1.5 g Au/t.

Saline water was drawn from nearby Lake Cowan, normally a "surface-dry" salt lake overlying a water reservoir contained within sediments and precipitated solids, notably gypsum. Extra channels and holding ponds were excavated to overcome both the shortfall in seepage replenishment rates and the low water reclamation rate from the plant tails, at times verging on negligible recovery. Low precipitation and hence runoff of surface water into the lake immediately prior to the commissioning period aggravated the water supply problems. The high dissolved solids content of the water, typically 100,000 ppm have not presented insurmountable problems within the processing circuit.

One minor problem encountered during commissioning included premature failure of pumps supplying process water from Lake Cowan. Severe corrosion within the pumps limited unit life to approximately six weeks.

More robust pumps now in use offer improved reliability and service. Areas of high abrasion within the plants were identified and corrective action taken. Pump impellors and discharge lines required upgrading.

Process water from Lake Cowan is rather acidic and pH values of 3.5 are not uncommon. The pH varies with the rainfall and the fraction of recycled tailings water in the process water. Lime consumption attributable to the ore accounts for the balance of lime used, 0.010% of free lime (as $Ca(OH)_2$) in the tailings solution allows for upward fluctuations in lime consumption during unmonitored periods, while maintaining a protective buffered pH for cyanidation. Lime consumption of up to 2 tons per day is not unusual during dry periods (4.5 Kg lime per ton ore).

As with lime consumption, cyanide consumption depends to some extent on the process water used. Typical consumption of cyanide is 0.3 Kg/ton ore processed.

A carbon-in-leach arrangement is employed in four tanks in series with a six hour retention itme, although cyanidation is generally complete after the first two hours.

Since carbon is not reactivated after each desorption, losses in carbon activity are compensated for by increasing carbon concentration in the pulp. Fresh carbon addition is made when soluble gold in the tailings rise above 0.05 mg/l. Initial gold loading averages 1500 g Au/ton however severe fouling of the carbon after several cycles reduces its activity to a point where only 1000 g Au/ton carbon is achieved. This was also affected

by the fact that acid washing was not carried out at the custom elution plant used to desorb the gold from the carbon. It was believed by Australis Mining personnel that the highly saline process water is responsible for some of the observed reduction in carbon activity, but this was not confirmed.

Periodic reactivation (about every 5 cycles) and acid washing with 5% HCl with every desorption cycle appears to allow consistent and reasonable gold loadings and soluble gold control in the tailings is also easier to manage.

It is not known whether this Australis Mining NL operation is still in production since at 1.5 Au/t the headgrade was low for a 400 tpd CIP operation, however if it is, more information can be requested from:

Norseman WA

Western Australia - Summary

1) Western Australian goldfields in general are short of water of good quality. Water pumped 350 miles from Perth is expensive and there is a limit to its availability. Locally available water is often extremely high in TDS.

2) Depending on the price of water and its availability, various measures to enhance water recovery from tailings and effluents become economically attractive in relation to purchasing fresh water. So far however there are no known sophisticated water treatment installations to reclaim water from tailings and to make it and contaminated effluents usable.

3) Numerous possible measures are available to improve recycled water quality which could be installed at a not too exorbitant cost. Some are simple such as segregation of cyanided and non-cyanided effluents. Others are more costly and may involve new technology with which these operations are not familiar.

4) Incentive to recycle more water and treat it will increase if it becomes available on a tighter allocation or if the cost of available fresh water goes up, but there is a limit to how much Western Australian operations can afford to pay for water.

5) Each site specific case must be evaluated on its own merits depending on ore characteristics, metallurgical process performance, availability of alternate water supply etc. Cases are reported e.g., Australis Mining at Norseman, where high TDS can be used for CIP with satisfactory results.

CANADA

Canada is a huge country mostly with cold to extremely cold winters. Some parts of Canada have a significant net precipitation while other parts are arid. Gold and silver operations are located in each of these climatic regions, although the main gold producing areas are faced with too much rather than too little water.

Gold Production in Canada

Northwest Quebec:	e.g., Around Val d'Or
Eastern Ontario:	e.g., Around Kirkland Lake, Timmins, Detour Lake, etc.
Central Ontario:	Hemlo District, Campbell Red Lake
British Columbia:	Several Small Gold Mines
Northwest Territories:	Giant Yellowknife Mines Con Mine at Yellowknife Lupin Project of Echo Bay Mines
Yukon Territory:	Several Placer Deposits

Silver Production in Canada

Most of Canada's silver production is believed to come as a coproduct with flotation concentrates of copper and lead recovered from complex sulfide ore deposits. These are located in the main mining districts and are spread out from New Brunswick, (Heath Steele, Brunswick Mining and Smelting Corp.) through Quebec (to include Noranda and Mattagami operations of Noranda) then through Ontario north of Lake Superior (including such Noranda operations as Geco and Mattabi). The largest of all is Kidd Creek Mines at Timmins.

Silver is also produced in sulfide base metal concentrates at several mines in British Columbia including Equity Silver.

Based on general observations made during a 1984 tour through the Canadian Mining districts the main characteristic of water management practices associated with Canadian gold operations is catering to the cold climate and concern about toxic effluent discharges to lakes and streams. Canada's Federal environmental regulations are promulgated under the Fisheries Act and are unquestionably fish-oriented. Canada has 37% of the world's surface fresh water resources. Although there are currently no Federal regulations regarding cyanide in effluents, these are under review. Any major cyanide damage to

the environment, especially fish, at this time would be likely to result in pressure on regulators and stricter ultimate rules. Two or three cyanide leach plants have been shut down at different times in the recent past due to concern about cyanide leaks to surface waters.

The Canadian federal Environment Protection Service has gone to great lengths to finance and support plant-scale trials of cyanide destruction or removal processes including alkaline chlorination, SO_2-Air cyanide removal and electrolytic removal of cyanide. These are described in Chapter 40 on cyanide removal.

Unfortunately Canadian winters are so cold that natural degradation of cyanide is unlikely to work for much of the year; six months of the year at Yellowknife.

During springtime when the ice and snow melt, large quantities of excess water runoff must be dealth with, although it also acts as a diluent.

Canada is not short of land space nor water. Some mining companies build very large tailings ponds to contain their tailings and effluents through winter as well as spring runoff. In summer natural degradation gets a chance to work and may be helped along by effluent treatment facilities to remove or destroy cyanide, base metals and arsenic as well as for pH adjustment. The natural degradation process was modelled by SIMOVIC, et al. (1984).

With so much water available, it seems that Canadian operations use more of it resulting in more effluent to treat and discharge.

Some of the older Canadian gold mines have no treatment plant for their effluent and rely on natural degradation. All new gold mining operations have, however, installed cyanide treatment plants with the exception of Echo Bay Mines' Lupin project in the Northwest Territories which employs a hugh shallow impoundment for natural degradation in summer.

Whereas Western Australian gold operations are likely to treat effluents and tailings so as to recover more water for recycle; and whereas South African operations may have to focus on limiting TDS in discharged minewater, the Canadian gold industry is concerned about disposing of tailings and effluent in a way that protects their fish. Regulatory limits are accordingly particularly strictly enforced at the headwaters of the more important salmon streams.

Of all the gold mining countries of the world, Canada is more concerned about cyanide excursions and heavy metal contamination of surface waters. Although a relatively small producer of gold by world standards, more cyanide destruction facilities have been installed at Canadian gold mines than in any other country. At last count there were eight plants, if Western Mines facility is included (which destroys cyanide in base metal

flotation effluent), but of these, two no longer operate. One has shut down and the other no longer uses cyanide.

Canadian regulations recognize that zero discharge is impossible for most Canadian mines. Canadian regulations seem also to recognize that mining is an essential part of their economy. The impression gained from regulators in Canada is that they are seeking to find out what can be done and the best economic way of achieving it.

PROCESS FOR DEGRADATION OF CYANIDE

Canadian experience particularly as orchestrated by Environment Canada has been largely responsible for stimulating improved insight into cyanide toxicity effects, cyanide determination techniques and cyanide decomposition or removal methods.

Since cyanide is the subject of a whole separate chapter, it is not discussed here again, except to refer to the plants that use cyanide destruction processes and to list a few Canadian experts in this field.

CANADIAN CYANIDE REMOVAL PROCESSES

Company	Location	TPD	m^3/d Treated	Process
Mosquito Creek	BC			Alkaline Cl_2
Scottie Gold Mine	BC			INCO SO_2-Air
DuPont Exploration	Baker Lake, BC	Now Closed		INCO SO_2-Air
Carolin Mines		No Longer Uses CN^-		INCO SO_2-Air
INCO	McBean, Quebec			INCO SO_2-Air
Western Mines	Campbell River, BC			Alkaline Cl_2
Giant Yellowknife	Yellowknife, NWT	1,250		Alkaline Cl_2
Cominco Con Mine	Yellowknife NWT			FeS
Projected				
Noranda	Hemlo	1,500/4,000	341/545	SO_2-Air
Kiena Gold Mines Ltd.	Ontario		Pulp	Emperor SO_2
Equity Silver Mines	British Columbia			Alkaline Cl_2

Canadian ores are not all free milling. Those at Giant Yellowknife Mines Ltd. require flotation and roasting as they do at Campbell Red Lake Mines. Formerly the Con Mine in Yellowknife also had a roaster, but now treats non-refractory ores. Pamour Schumacher

mill in Timmins also adopts a non-roasting hydrometallurgical approach to relatively refractory ores.

There was a time when companies did not need to worry too much about the effect they had on the environment. Cominco's Con mine recently invested $13 million to install a processing facility to treat 30,000 tons of arsenical flue dust collected from the baghouse on their roaster - neither of which are in operation today. Although it is hoped to profit from the sale of arsenic and an incremental gold production, the alternative need to prevent arsenic excursions from the sludge ponds on the site was an additional incentive.

There are several very interesting water management concepts that are put into practice at Canadian gold recovery operations as needed to meet site specific requirements. A reasonable cross section of water management practices in Canadian gold recovery operations is gained through a summary of the following:

1) Noranda Mines at Hemlo
2) Scottie Gold Mines
3) Carolin Mines
4) Dome Mines, Timmins Ontario
5) Giant Yellowknife Mines, NWT
6) Con Mine Yellowknife NWT
7) Echo Bay Mines Lupin Project, NWT
8) Lac Minerals, La Mine Doyon, Quebec

HEAP LEACHING

Heap leaching of gold ores is attracting a lot of attention in Canada at this time. Water management is a major consideration for heap leaching in the Canadian climate with its frozen winters and net precipitation in many areas.

It is believed that heap leaching may be carried out indoors at far northern locations but to date no such project is in operation in Canada.

Anaconda minerals did bring one heap leaching project into operation on the eastern seaboard of Canada; this was their Caribou project in Nova Scotia. This operation was designed to be installed and completed within one summer season to avoid problems with freezing and thawing. It is believed that much useful data was gathered, but it will have to wait for a future evaluation.

Water management for Canadian heap leaching projects are not discussed here. Sponsors are referred to the following consultants known to have worked on this aspect.

NORANDA HEMLO PROJECT

The mines and mills under development in the Hemlo district by NORANDA, LAC MINERALS and TECK Corp. will collectively about double the Canadian gold production and the tonnage of ore mined and milled for the purpose.

These major mills will treat their tailings and discharge effluents, and it will be interesting to learn how they propose to do so. The mines and mills are still under development, and it was not possible to get the full details as to how they propose to treat their tailings and how they will manage their effluents and water, although a rough outline of NORANDA's effluent treatment facility at Hemlo is shown below.

Hemlo gold ores contain relatively large amounts of environmentally undesirable metals. For example Noranda's Hemlo ore is rich in pyrite and has the following approximate level of metals:

Gold	4 - 16 g Au/t
Silver	0 - 2%
Mercury	16 g Hg/t (Ave.) as cinnabar
Molybdenum	0.03 - 0.04% MoS_2
Zinc	0.002% Sphalerite (Ave.)
Antimony	0.02% Stibnite (Ave.)
Arsenic	0.02% Arsenic (Ave.) 4-40 g/t Realgar

The metallurgical gold recovery circuit and effluent treatment plant design have had to take the ore characteristics into consideration as well as the environmentally sensitive location adjacent to a provincial park on one side and an Indian fishing ground on the other.

Water management for the operation requires an integrated plan including a partially lined tailings pond with seepage collection and return, mine backfill, tailings treatment to remove molybdenite with some of the arsenic, mercury and antimony sulfides, and finally effluent treatment for cyanide and residual soluble antimony and arsenic removal.

6.0 EFFLUENT TREATMENT

6.1 GENERAL

The mine and mill operation will produce four wastewater effluents: tailings decant, mine drainage water, runoff from the site, and sanitary sewage.

During operations, effluent from the tailings area as well as mine water will be treated in the effluent treatment plant.

Site drainage will be directed to a stormwater holding pond where it will be monitored and discharged when required to Cedar Creek. Sanitary sewage generated during construction and operation will be treated in a package treatment plant prior to discharge to Cedar Creek.

Tailings Effluent Treatment

The chemical characteristics of the tailings decant can vary considerably since the effects of natural degradation, dilution and chemical reactions in the tailings area will take place at varying rates throughout the year. Pilot plant test work was carried out at Lakefield Research of Canada on the gold extraction process, from which analyses of barren solutions from the carbon adsorption were made. The results of these analyses and leaching tests of the tailings material were combined to provide an estimate of the inflow to the effluent treatment plant, as shown on Table 6.1. The effects of aging in the pond and dilution were also considered to some extent.

Various processes which would reduce these chemical components to acceptable levels were evaluated. Preliminary conclusions are that a two step process will be required: the first one to treat for removal of free cyanide and metallo-cyanide complexes, and the second to treat the more persistent heavy metals. Minewater will be introduced for treatment in the second step of the process.

Noranda Mines Limited
Hemlo Project

JANUARY 1984

Introduction:
Noranda Mines Limited, Hemlo Project is developing an underground mine and milling complex to mine and process gold bearing ore. Located within 55km of Marathon, White River and Manitouwadge, the orebody has reserves presently totalling about 20 million tonnes, promising a mine life of some 20 years. The initial mining and milling rates will be 1000 tpd expanding to 3000 tpd. An expected workforce of 350 people will be required.

The proposal to mine the orebody and to treat the ore was developed over the past year as a result of studies in many disciplines including geology, mining methods, metallurgy, geotechnology and environmental science. Results from all of these studies form the basis of the present engineering design and operating plan. Ongoing discussions with the various government agencies and public are an important part in identifying the concerns that have to be addressed in the operating plan.

Noranda's final plan to develop and operate the Hemlo Project is now being discussed at public information sessions which are open to all parties concerned. Final Certificates of Approval, required under Section 24 of Ontario Water Resources Act, will be issued by the Ministry of Environment after consideration of public input and thorough review of detailed engineering plans.

A brief description of each area of the proposed operation is given below.

Project Development
In order to meet the target start-up date of January 1985, an ambitious engineering and construction schedule is underway. Construction manpower is estimated to peak at 700 men during the summer of 1984. Temporary housing facilities for this workforce is provided on site. Permanent manpower required for the mining and milling operations will increase gradually to 200 for the January 1985 start-up. This number is expected to increase to 350 in 1987. Housing will be provided in the existing communities.

Mining:
The orebody can be thought of as a long, thin rectangular book dipping northward at an angle of 70° to the horizontal. The planned mining method is blasthole stoping with delayed fill. A stope is an underground excavation that is made by removing ore from the surrounding rock following a detailed drilling and blasting plan.

After each blast, the broken ore, falls to the bottom of the stope, where it can be recovered for transport to the underground primary crushers and crushed to less than 6 inch fragments.

After the ore has been drawn from a stope, the opening is filled with rock followed by cemented tailings which fill the voids and consolidate the rock fill.

A shaft is being sunk to a depth of 1,455 metres to access the ore. The shaft contains two 16 tonne productions skips, a 40-man single deck cage, a pipeway, manway and a counterweight. To supply fresh air to the working areas, a push-pull ventilation system will be used. Fresh air and exhaust fans will be located on surface. The fresh air supply will be heated during the winter with a propane heating system and waste heat from the mine compressors.

Hemlo project

Proposed Tailings Plan, Pipeline Route

Access Road Profile

noranda

Milling:
The on-surface crushing circuit reduces the ore to less than 1/2 inch. To form a slurry water is added and the ore is ground to a fine sand in the grinding circuit. The slurry is thickened before being pumped to the leaching circuit, a series of steel tanks located outside the mill building. Here the gold is selectively dissolved into solution. The leached slurry then flows to the carbon-adsorption circuit where the gold is adsorbed onto the activated carbon surface. The loaded carbon is stripped of the gold at high temperature and pressure to form a concentrated solution for the electrowinning circuit and refining step.

In addition to gold, the ore contains molybdenum which will be separated from the slurry by conventional flotation techniques. Pilot tests conducted to date have not been successful in producing a saleable molybdenum product and additional studies will be done when the milling operation starts up.

In addition to gold, the ore contains molybdenum which will be separated from the slurry by conventional flotation techniques. Pilot tests conducted to date have not been successful in producing a saleable molybdenum product and additional studies will be done when the milling operation starts up.

After separating the molybdenum, the tailings slurry is pumped to the backfill plant where the fraction of coarse sand (about 40%) is removed for use as backfill in the underground mine. The remaining 60 percent is disposed of in the tailings impoundment area.

Tailings Disposal
The tailings slurry is pumped to the impoundment area located about 2.8 km northwest of the plant. Out of a possible five sites, narrowed down from a total of twelve, this particular site was chosen since it offered the best combination of desirable features. The major criteria used to help evaluate the alternative disposal sites include:

1. adequate capacity to contain the tailings produced during the life of the operation.
2. close proximity to the mine site.
3. minimal watershed area to reduce the quantity of water coming into contact with the tailings.
4. naturally occurring features to enhance the suitability of the site for containment.
5. status and land ownership questions had to be resolvable within reasonable time and economic limits.

The chosen tailings pond site is contained in a small valley just west of Cedar Creek. The main dam design ensures stability and minimum seepage. Techniques to achieve seepage control will include an excavated cut-off trench extending down to the bedrock, cement grouting of the bedrock and installation of a high quality seal, comprised of a synthetic liner and a layer of til on the upstream side of the embankment. Seepage which does by-pass the main dam structure will be intercepted in the seepage collection pond and pumped back to the tailings pond.

During operations, in addition to continuous computer monitoring, daily visual inspections of the tailings and reclaim water pipelines, pumps and dams will be carried out.

Hemlo project

Water Flow Diagram

noranda

3312

Water Recycle
Water recycle is an effective method of minimizing environmental effects by reducing total fresh water needs and by reducing the amount of water ultimately discharged to the environment. To this end, Noranda has been able to provide about a 70 percent recycle rate in the process.

Water Supply
Noranda, jointly with two other companies active in the area, is conducting a water supply study to formulate a proposal for government approval. The study will focus on the ability of the Cedar Creek system to satisfy the requirements and interests of the mining operations, and of the existing cottage owners within the Cedar Creek drainage basin.

Water Treatment Systems
Plant site run-off water will be channelled to the sedimentation pond by a system of ditches for the removal of suspended solids prior to discharge.

A biological treatment system is being used to treat sewage from all plant site services to meet the Ontario Ministry of Environment's guidelines. Water from the tailings pond will be returned to the plant site for recirculation and treatment in the effluent treatment plant. The proposed effluent treatment system uses the most up-to-date technology available to reduce contaminants to levels below the Ontario Ministry of Environment guidelines. Two treatment steps are being used to remove cyanide and heavy metals. The first step is the SO_2 process which destroys free cyanide and metallo-cyanide complexes. The second step removes the more persistent heavy metals using a ferric iron co-precipitation process.

The final effluent will be discharged to Lim Lake in the White River Watershed as requested by the Ontario Ministry of Environment.

Reclamation:
A program of reclamation and stabilization of the mine site and tailings disposal area will be carried out after decommissioning of the mine to ensure stability of the site, safety to man and wildlife and protection of the environment.

SCOTTIE GOLD MINES LTD.

Post Office Box 308
Stewart, B.C. V0T 1W0

Scottie Gold Mine is located at a high elevation in the Canadian Rockies near Stewart, BC. The mine is on a steep mountainside which is prone to avalanches in winter, consequently the complete mill has been erected inside a giant underground cavern.

Tailings from the 200 tpd high grade operation are discharged into a glacial lake. The outlet from the lake is shut off by a glacier for most of the time. However, in spring and summer as melt runoff fills the lake above a certain level, the ice is floats and releases the contents of the lake including the tailings into the river below. The river flows across the Canadian border into Alaska where it becomes a salmon stream which discharges into the ocean.

Scottie Gold leaches ground ore in cyanide and then filters the pulp. Gold is recovered by Merrill-Crowe and tailings were discharged to the lake. Up to 130 m^3/d barren bleed was treated by chlorination before being discharged to the lake.

Scottie gold ore contains quite high levels of pyrrhotite which results in a considerable ferrocyanide concentration which is not decomposed by alkaline chlorination. It ties up a considerable amount of cyanide which reaches the tailings pond reporting as CN_{Total}.

The filtration step, by all accounts, used to result in relatively poor washing of the filtercake which also resulted in some cyanide and even soluble gold values being discharged with the tailings, but the main metal and cyanide contamination was with barren bleed.

DISADVANTAGES OF ALKALINE CHLORINATION

1) Alkaline chlorination proved unable to achieve low total cyanide levels in the lake because it did not destroy ferrocyanide.

2) The chlorination process was installed underground and resulted in an unpleasant operator environment - watering eyes, etc. were one uncomfortable effect.

3) Solid chlorine forms such as $Ca(OCl)_2$ were used, and these had to be added in large quantities with the result that the tank would "freeze" solid.

4) Not enough chlorine could be added to kill all the cyanide without safety problems.

On account of cyanide (CN_T) buildup in the lake the operation was shut down temporarily by the BC government.

The existing alkaline chlorination tanks were converted by INCO Tech Ltd. to SO_2-Air cyanide removal to treat the barren solution. With the addition of one more air sparged tank the tailings pulp has been added into reactor II to treat it as well. Final effluent of 0.1-1 ppm CN_T with low metal values are achieved consistently which works out to a removal of over 99.5% of the cyanide in the incoming streams. The process has been described by DEVUYST & CONARD (1984).

The important point as far as water management is concerned in this case is that since the tailings are discharged to a lake, cyanide must be destroyed or removed in the total tailings and barrens and not just the tailings pond decant.

In this case the treated effluent from the cyanide destruction plant, although impressive, does not consistently achieve levels typically imposed on gold plant effluents. Regulatory authorities have undoubtedly taken into account the very large dilution of tailings by runoff water and snowfall.

CAROLIN MINES LADNER CREEK OPERATION

Carolin Mines Ladner Creek mill near Hope, BC treats about 1300 t/d ore at about 0.1 oz Au/t. A concentrate is recovered by flotation which was leached in cyanide. After cyanidation the tails were floated a second time to recover a graphite concentrate. Barren bleed was typically 150 m^3/d.

Process water is obtained by recycling tailings pond decant water. This requires removal of any cyanide which would otherwise depress pyrite in the flotation step.

Barren bleed was initially treated by alkaline chlorination, but washed tailings containing 5-10% of the cyanide bleed were discarded to the tailings pond without treatment.

Excess pond decant water was treated in a second alkaline chlorination circuit and then dechlorinated and pH adjusted prior to discharge to Ladner Creek. The permit to discharge tailings pond decant was limited to a maximum level of contained ferrocyanide. Iron cyanide levels were found to increase during winter months which created a serious problem for Carolin during spring runoff.

The problems were aggravated by the fact that Carolin Mines is located on the headwaters of the Fraser River. The British Columbia government was anxious about ferrocyanide in effluents to shallow streams in which they believed that free cyanide might be released by

UV in sunlight. With this restriction on discharge in force, the levels were building up and after a third tailings spill, the plant was temporarily shut down.

Carolin Mines had been accused of being responsible for fishkills in the stocked river in 1982. They were fined and temporarily shut down by the BC government.

The INCO SO_2-Air process was licensed in 1983. The existing alkaline chlorination process was converted for this process using auxiliary aeration agitation. Addition of $Na_2S_2O_5$ was in proportion to the barren flowrate and its cyanide content. In this case no copper sulfate addition was needed and lime was added on demand by means of a titrator-pH controller as described by DEVUYST & CONARD (1984).

Later on, tailings solids were also treated at Carolin. This was done by adding excess $Na_2S_2O_5$ to treated barren overflow as it entered the tailings box. Some $Na_2S_2O_5$ was also added to the aerated mix tanks for which flotation cells were employed.

Subsequently, cyanide soluble iron levels increased dramatically in Carolin Mines ore and in the tailings to the extent that improved agitator tanks were needed. At that point, Carolin Mines elected to stop using cyanide and, instead, to ship their flotation concentrate to a smelter.

The costs of alkaline chlorination and SO_2-Air cyanide removal at Carolin Mines were not determined, but these must be quite substantial, including royalties, to justify shipping a concentrate with only ±1 oz. Au/t to a smelter.

The arrangement and results of the SO_2-Air process using the converted alkaline chlorination process are shown in the following table from DEVUYST & CONARD (1984).

DOME MINES, TIMMINS, ONTARIO

Dome Mines at South Porcupine, Ontario is one of the older mine-mill operations in Ontario and is of interest because they practice natural degradation of cyanide. This aspect has been extensively studied by Environment Canada as described by SCHMIDT et al. (1981) and SIMOVIC, et al. (1984).

Dome Mines constructed a separate impoundment for their "barren bleed" in 1975 so that this cyanide and base metal rich effluent could be retained and released only during the months April to November during which natural degradation takes place. The barren bleed pond was ultimately sized to contain 75% of the bleed discharged between December and March and was the subject of a joint assessment program. The Environment Canada report contains valuable information and is reproduced here in its entirety. Additional information on natural degradation is included in a more recent paper by SIMOVIC, et al. (1984).

It is concluded from this set of data that whereas separate impoundment of barren bleed does reduce cyanide and metal levels considerably in the final discharge, this process does not seem to be able to maintain the metal and cyanide removal consistently enough to be able to recommend relying on natural degradation alone to meet the anticipated regulatory limits in cold climates such as Canada.

The results of the monitoring program at Dome were:

(1) Cyanide content decreased from 65 ppm in March to 0.05 ppm in August.
(2) Temperature variation was 6°C.
(3) pH dropped from 10.5 to 7.0.
(4) pH drop was due to natural carbonation and hydrolysis of thiocyanate.
(5) Over 90% of the cyanide decrease was attributed to volatilization of molecular HCN.
(6) Some photodecomposition of ferrocyanides occurred.

The results are extremely important because they show that cyanide does not persist in the environment, and consequently, long-term effects are likely to be negligible (HUIATT, 1984). RANDOL INTERNATIONAL LTD. raises the question, "If natural degradation is due to CO_2 dissolution effects causing volatilization of cyanide, could this process perhaps be enhanced to speeded up through small CO_2 additions to decanted effluents in the pond or at the final discharge point?"

It is understood that the Ontario Provincial Government - Ministry of the Environment is relatively circumspect as to where they allow the sampling point for "final effluent" to be, depending on the sensitivity of the particular operation and its location as an environmental threat.

NATURAL DEGRADATION OF CYANIDES IN GOLD MILLING EFFLUENTS

J.W. Schmidt[1], L. Simovic[1] and E. Shannon[2]

Presented at the Cyanide and The
Gold Mining Industry Seminar
January 22 to 23, 1981

INTRODUCTION

Since 1973, Environment Canada has been concerned with the development and demonstration of suitable technologies for the removal of toxic contaminants from gold mine effluents. Contaminants of concern are cyanide, zinc, copper, nickel and arsenic. Several alternative technologies (alkaline chlorination, ozonation, ion exchange, electrochemical and others) which have potential for treating gold mill effluents have been outlined earlier in this seminar. In addition, The Environmental Protection Service (EPS) and Giant Yellowknife Mines (GYK) in a joint program have carried out pilot studies on alkaline chlorination and metal precipitation on various mine-mill effluents (Erkku and Price, 1979).

In early 1979, recognizing that natural processes may play a key role in determining the fate of cyanide and metal discharges from gold mines, EPS commissioned a literature review (IEC, 1979a) of the factors affecting the natural degradation of free and metal-complexed cyanides from gold milling effluents. It was apparent from this review that tailings pond or separate liquid impoundment areas had a high potential for cyanide removal from gold mill effluents on individual high cyanide stream (e.g. "barren bleed"), and in fact, several mines in Canada were using such a system.

One of these mines was Dome Mines at South Porcupine, Ontario, which had constructed a separate impoundment area for their "barren bleed" in 1975 (Pyke, 1978). The decision to provide separate barren bleed containment was based on observations (prior to 1975) that natural degradation of cyanide was occurring in a retention pond downstream of their tailings ponds. This degradation was found to occur primarily during the months of April through November. Under ice-cover little, if any, degradation was observed.

Although the Dome "barren bleed" impoundment experienced some operational problems during 1975 through 1979, the pond was ultimately sized to contain 75% of the bleed discharged between December and March. In 1978/79, the system operated successfully and in August 1979 the Wastewater Technology Centre (WTC) approached Dome Mines regarding a possible joint assessment program for the 1979/80 operating season as part of Environment Canada's program to develop suitable technology for the treatment of effluents from gold mills.

A cooperative study was agreed upon with Dome Mines Limited with the overall objectives of the study being:

1) to assist the mine in a better understanding of the processes ("natural degradation") which are occurring in their effluent treatment systems, and
2) to support the Gold Producers Task Force by examining the applicability of the Dome Mines technology for the removal of cyanide and other undesirable constituents from gold mill effluents, to other gold producers.

Specific study objectives relating to the operation of the "barren bleed" impoundment area and the tailings pond were:

1) To determine the degree of cyanide conversion/degradation in both systems;
2) To determine the extent of reduction of other undesirable constituents (e.g. metals) in both systems;
3) To examine the factors affecting the natural degradation of cyanides;
4) To relate the data generated by this study to the existing long-term data base (eg., data provided to the Ontario Ministry of the Environment over the years).

At this stage, this paper is a progress report for this project. Although data have been collected over a period of 14 months, results are still being assessed and correlated and it is expected that sampling will be undertaken again in 1981.

DEGRADATION MECHANISMS

Several studies on the fate of cyanide in the aquatic environment have documented that cyanide is not persistent. This natural degradation in receiving waters is generally attributed to a combination of physical, chemical and biological mechanisms including volatilization, oxidation, biodegradation, photodecomposition and conversion to thiocyanate. The relative magnitude of each mechanism appears to be governed by aquatic system variables such as pH, temperature, lake or stream morphology, and water chemistry.

Detailed literature reviews on the fate of cyanide (Ecological Analysts Inc., 1979) and on the natural degradation of cyanide as it relates

to gold mining effluents (IEC, 1979a) have been compiled and should be referenced for further detail on specific mechanisms. Factors which are potentially relevant to type of behavior observed during this study are discussed in the following.

Volatilization

Free cyanides exist in aqueous solution in a cyanide ion (CN^-) and hydrocyanic acid (HCN) equilibrium

$$HCN \rightleftarrows H^+ + CN^-$$

The dissociation constant for HCN is given in the following equation:

$$Ka = \frac{[H^+]\,[CN^-]}{[HCN]} = 4.93 \times 10^{-10} \quad (pka = 9.3)$$

The equilibrium and the relative distribution of CN^- and HCN is pH dependent. For example, at pH 7 to 8, 95 to 99.5% of the free cyanide exists as molecular HCN. Molecular HCN has a readily high vapor pressure and therefore, can readily be volatilized to the atmosphere, even from stagnant solutions. Dodge and Zabban (1952) and the Chester Engineers (TCE, 1977) have conducted extensive investigations of the factors influencing volatilization of cyanide. In general, reduced liquid depth to surface area ratios, decreased pH, increased temperature and increased turbulence will accelerate volatilization.

Metal cyanide complexes tend to dissociate into free metal ion and free cyanide. The extent of dissociation can be predicted from the appropriate dissociation constants. This approach is somewhat simplistic, as the hydrolysis of CN^- to HCN at the pH's found in natural waters will tend to shift the equilibrium so that more free cyanide (as CN^- + HCN) will be in solution than predicted by the use of the dissociation constant alone. However, the important factor in the rate at which cyanide bound in the complex exchanges with free cyanide in solution. MacDiarmid and Hall (1954a,b) observed that the rate of exchange of ^{14}C labelled cyanide was independent of CN concentration, which is consistent with a rate of exchange

governed by a step involving the slow dissociation of the complex. The rate of exchange was found to increase with a decrease in pH as well as by increasing the intensity of illumination by lights. In general two and four coordinate complexes exhibit rapid exchange rates while octahedral (hexa-cyano) complexes have slower rates. The time period required to achieve equilibrium ranges from approximately 1 day for $Ni(CN)_4^{-2}$ to 250 days $Fe(CN_6)^{-4}$.

Oxidation

Although chemical oxidation of free cyanide is a commonly employed treatment method for cyanide containing wastewaters, little data are available regarding the oxidation of cyanide in natural waters. Investigations by Pipes (1975) and Owerbach (1978) and others suggest that under aerobic conditions a certain amount of free cyanide may be converted to cyanate. It is not clear whether this conversion of cyanide to cyanate can occur non-biochemically.

If oxidation of cyanide were occurring, then the probable reaction product would be cyanate in accordance to the simplified equation:

$$HCN + 1/2\ O_2 \rightarrow HCNO$$

As shown by Hendrickson and Daignault (1973), cyanate can be hydrolyzed to carbonate and ammonia. This can occur at a pH of about 8.5.

$$HCNO + H_2O \rightarrow NH_3 + CO_2$$

Biodegradation

Biodegradation of cyanide can occur under either aerobic or anaerobic conditions Nesbitt and Wagner (1959) identified three bacterial types which were capable of cyanide decomposition. Later, Towill et al (1978) observed that there appears to be a wider variety of bacteria that degrade cyanide (generally free cyanide) rather than synthesizing it. Cyanide degradation at pH's as low as 5.3 and as high as 10.0 have been observed by Furuki et al (1972).

Under aerobic conditions cyanide biodegradation can be depicted simply as:

$$HCN + 1/2\ O_2 \xrightarrow{enzyme} HCNO$$

The resultant HCNO can then be further hydrolyzed as follows:

$$HCNO + H_2O \xrightarrow{enzyme} CO_2 + NH_3$$

A suggested pathway for the anaerobic decomposition of cyanide leads to thiocyanate formation followed by hydrolysis, i.e.

$$HCN + S \longrightarrow HCNS$$
$$HCNS + 2H_2O \longrightarrow H_2S + CO_2 + NH_3$$

Photodecomposition of Complex Cyanides

Cyanide forms complexes of varying degrees of stability with many metals. Metals of primary interest in gold mining effluents include zinc, copper, nickel and iron. Some of these complexes particularly those with iron, (ferro- and ferricyanide) are very resistant to decomposition.

It is evident from the previous discussion that most of the potential cyanide degradation or removal mechanisms apply to the free cyanide. In general, it is necessary to dissociate or break down cyanide-metal complexes to the metal and free cyanide components before cyanide removal can occur from an aquatic system. The rate and degree of dissociation of a particular complex is generally dependent upon pH and total cyanide concentration. Broderius (1973) showed that dissociation to free cyanide is greater for most cyanide-metal complexes under acid conditions. In a later study (Broderius, 1978) it was observed that ultraviolet irradiation accelerated the decomposition of the ferricyanide. The decomposition was relatively rapid, e.g. half-lives for iron-cyanide complexes of 50 and 20 minutes were observed for fall and summer mid-day conditions respectively for a lake surface in Minnesota.

Factors such as light penetration as affected by turbidity, color and depth, intensity and wavelength of light, angle of light incidence and cloud cover, will determine the impact of photodecomposition in a specific body of water.

Cyanide-Thiocyanate Reactions

According to Ford-Smith (1964) there are some 28 elements which are capable of forming complexes with cyanide with some 72 metal-cyanide complexes possible. The most important complexes in gold mining effluents appear to be those of iron, copper, zinc, nickel, cobalt and cadmium. Gold and silver are excluded since their effluent losses are minute compared to the referenced metals.

The formation constants (log k) for metal-cyanide complexes vary from a low of 5.48 for $[Cd(CN)_4]^{-2}$ to a high of 42 for ferrocyanide. The formation constants for metal-thiocyanate complexes tend to be much lower than the corresponding metal-cyanide complexes. It follows that if both cyanide and thiocyanate are present in solution the cyanide complexes will exist in solution preferentially to the respective thiocyanate complexes. In general, this is the case in most gold mill effluents.

In the absence of cyanide, the thiocyanate complexes will be present. Many of the metal-thiocyanate complexes are insoluble; therefore, this mechanism may play a role in the removal of zinc, nickel and copper in effluent holdings ponds.

Study Site

The Dome mine, located about 1.5 miles (2.5 km) southwest of the town of South Porcupine, Ontario, began operations in 1912 and except for two short delays, has been in operation continuously to the present day. Both gold and silver are recovered with the chief gangue minerals being quartz and ankerite with about 2.5% pyrite and/or pyrrhotite, (Pickett, 1978). The mill, with a capacity of 2 000 tons (1 820 tonnes) per day empolys the process of cyanidation and amalgamation to recover the gold. Approximately half the product is recovered in each process. The circuit is fairly conventional with crushing, grinding, amalgamation, leaching and gold recovery

by zinc precipitation (Figure 1). The tailings are discharged to a conventional tailings pond system (Figure 2) with approximately 30% being used as backfill underground. The waste barren or "barren bleed" amounts to 800 tons (730 tonnes) daily or 110 Igpm (0.5 m^3/min) and contains approximately 95 mg L^{-1} CN (Pyke, 1978).

The "barren bleed" is normally discharged with the tailings to the tailings pond except that during the colder weather, November through March, 75% of the barren bleed is discharged to a separate holding pond (Figure 2), as mentioned previously.

The "barren bleed" holding pond consists of two interconnected sections, a shallow section with a fairly large surface area and a deep section with about 10% of the surface area of the shallow section.

For this study sampling locations were established to obtain samples influent and effluent from each system as well as within the holding pond (Figure 2). The collection of grab samples was initiated on September 5, 1974 and continued until November 12, 1980. The tailings pond was sampled weekly and the shallow section of the "barren bleed" holding pond was sampled weekly from September 5, 1979 to June 25, 1980, then daily until the pond was discharged in early October. Sampling of the deep section of the pond was initiated on a daily basis on June 11 and also continued until October. All sampling was carried out by Dome personnel.

The selection of parameters to be measured was based upon the requirement for basic mean flow data and the assumption of potential degradation mechanisms. The specific parameters measured are listed in Table 1.

Meteorological data were obtained from the Timmins airport station located approximately 10 miles (16 km) away. However, it was decided to augment these data with on-site data and a "met" tower with specific measuring equipment was installed near the holding pond in late June. This station provided direct measurement of rainfall, wind velocity, solar irradiation and air temperature.

Samples for bacterial counts and metal analyses were unpreserved but these latter samples were acidified prior to anlaysis. Samples for the analysis of CN_T, CNO and CNS were preserved by adding NaOH to raise the pH to 12.

RESULTS AND DISCUSSION

1. Tailings Pond System

Water Balance

The sole source of water to the tailings dam, with the exception of precipitation, is the mill tailings discharge. The volume of liquid discharged was computed on the basis of the tonnage milled and the "percent solids" pumped to the dam. Daily flows were calculated and converted to weekly mean values. Over the period of the study the weekly flow was found to be 845 $\pm$ 170 Igpm [3.8 $\pm$ 0.8 m^3/min]. Over the 61 week study period the total volume of liquid discharged to the tailings ponds was calculated to be 520 Igal (2.36×10^6 m^3).

The outflow from the ponds was not measured routinely. However, WTC personnel did conduct a one week tracer study to determine the residence time of the tailings pond and the volume of the outflow. The flow was

determined by measuring the velocity throughout a defined cross section in the outflow stream by using an "Ott Meter". It was found that the volume of the outflow agreed reasonably well with the inflow, therefore it was assumed that influent and effluent flow were equal over the duration of the study.

The residence time of the tailings pond was determined by injecting a lithium chloride tracer in the influent and measuring its concentration in the outflow. The results are presented in Figure 3. The mean residence time was determined as 70 hours or approximately 3 days.

Chemical Characteristics and Mass Loadings

Average and standard deviations data for the chemical and physical parameters measured on the tailings pond are summarized in Table 2. Data on the influent and effluent mass loadings for CN_T, CNO, CNS, Fe, Cu, Ni and Zn are presented in Table 3. In order to delineate the effects of not having the "barren bleed" discharged to the tailings pond, the data of Tables 2 and 3 have been divided into three seperate time periods. Mass loading plots for the tailings pond are presented in Figures 4, 5 and 6 for CN_T, Cu and Zn, respectively.

Removal of the "barren bleed" from the tailings pond influent tended to reduce the influent cyanide, thiocyanate, iron, copper, nickel and zinc concentrations by 37, 46, 27, 35, 57 and 65% respectively. However, effluent cyanide levels with and without "barren bleed" are not significantly different. This is probably due to the fact that most of the "barren bleed" is dicharged to the holding pond during less favourable conditions and the total "barren bleed" is only discharged to the tailings pond during a period when environmental conditions favour natural cyanide losses (degradation).

The influent cyanide loadings to the tailings pond are significantly higher during "barren bleed" periods (Figure 4). Effluent loadings tended to reach a minimum during June. The average cyanide removal through the pond was 65%. With the total barren bleed the cyanide loading reduction averaged 73% and without the bleed, 46%.

Effluent cyanate concentrations and loadings tended to increase during the warmer months suggesting that a certain amount of cyanide to cyanate conversion is occuring in the tailings pond. This effect is discussed later with respect to the holdings pond results.

Copper and zinc loadings increase during "barren bleed" addition periods (See Figures 5 and 6). In the case of copper there is a direct correlation between influent and effluent loadings. Nickel behaved in a similar manner as zinc, however, effluent zinc loadings were relatively insensitive to influent loadings over the study period (Figure 6). Overall zinc, copper and nickel reductions were 77, 33 and 19%, respectively.

The trend for iron appears to be one of warmer season iron retention and winter season losses with the net effect being no removal. This may be due to the carryover of stable iron-cyanide complexes during the winter when little or no photodecomposition occurs.

From the tailings pond data it is apparent that seasonal factors are playing a significant role in determining pond performance. Some of the potential natural degradation mechanisms which are probably important are discussed later with respect to the holdings pond data.

2. Barren Bleed Holding Pond

Water Balance

The importance of obtaining a water balance was recognized in the design of the study. Unfortunately, however, all the data to compute a balance were not available at the time of writing the paper. Those values that have been calculated are described in the subsequent paragraphs.

The volume of the "barren bleed" discharged to the holding pond was not directly measured but calculated from the number of days of discharge to the holding pond and the difference in the flow to the tailings pond without and with the "barren bleed". This flow was estimated by preparing a probability plot of the mean weekly flow values (Figure 7). The flow was estimated at 205 Igpm [0.9 m^3/min] and was discharged to the pond for 184 days. Dome Mines recently installed a flow meter and for a seven day period in January (1981) a mean flow of 155 Igpm [0.7 m^3/min] was recorded which agrees reasonably well with the calculated value.

Measurements of rainfall were made while the meteorological instrumentation was on-site from June 28 through October 3, 1980. The quantity of evaporation was calculated from the meteorological data. It was calculated that there was a net evaporation loss of 5.4" (14 cm). However, to calculate these values for the remainder of the study additional data have to be obtained and analyzed. This will be done in the near future. Additional data to compute the discharge volume from the pond must also be obtained.

Chemical Characteristics

Data on the concentrations of the various chemical parameters measured, as well as pH, temperature and suspended solids, are summarized in Table 4. The most significant of these mean values are those for the cyanide discharge to the holding pond and, after degradation has occurred, the discharge from the holding pond. For example the cyanide concentration decreased from 68.7 mg/L to 0.08 mg/L indicating 99.9% removal. The residual concentrations of Fe, Cu, Ni and Zn were 0.4, 0.1, 0.4 and 0.3 mg/L respectively. Metal removals were 88, 98, 80, and 97% respectively.

The concentrations of various cyanide and metal species are plotted in Figures 8 through 12 for the holding pond influent and for the samples

FIGURE 12 — IRON IN BARREN BLEED HOLDING POND

collected from the shallow section of the holding pond The striking feature of the graphs of the chemical concentrations is the decrease of the various constituent concentrations which occurs after filling of the pond has been completed. This phenomenon begins in April and continues throughout the summer and appears to be related to the rise in temperature and the drop in pH which occurs during the same period (Figure 9). Iron, however, does not appear to follow the same pattern. The rate of removal of constituents in the deep section paralleled, but lagged (by about 35 to 40 days) that of the same constituents in the shallow section.

Cyanide Removal

The removal process began almost immediately after discharge of the "barren bleed" ceased (Figures 8, 10 and 11). In an attempt to determine what was occurring during the initial stage of cyanide disappearance, data from April 2, (the initial point for the cyanide removal process) were compared with data from April 30, when the ice cover had largely disappeared from the pond. These data are presented in Table 5. To determine the amount of CN^- ion which might potentially be volatilized, it was assumed that the metals present existed as metal cyanide complexes and that the residual cyanide concentration was therefore "free cyanide" available for volatilization. (Although this assumption, strictly speaking, is not correct because total metal concentrations were measured on unfiltered samples, it was considered that this would provide a maximum boundary condition for the metal cyanide complexes). The metal cyanide complexes assumed to exist where $Fe(CN)_6$, $Cu(CN)_3$, $Ni(CN)_4$, and $Zn(CN)_4$.

It should be noted that the pH was very alkaline throughout this period; pH 11.5 on April 2 and pH 11.4 on April 30. Conceivably, a significant proportion of "free cyanide" could have accumulated while the pond was ice covered. The data in Table 5 suggest that 25.3 mg/L of the CN_T was volatilized. About 8.0 mg/L evolved from the dissociation of the metal complexes to produce free cyanide which was subsequently volatilized.

TABLE 5. HOLDING POND CONCENTRATIONS* DURING INITIAL CYANIDE REMOVAL

	2 April 1980		30 April 1980		Difference

* all concentrations in mg/L

Figure 13 provides a perspective of the interaction of the various shallow pond parameters from April 2 through September 17. Trends are shown for cyanide, cyanate, thiocyanate, pH and metals. On August 6 the CN_T concentration reached 0.05 mg/L. After April 30, the pH of the system began to drop, reaching a value of approximately 8.3, the pH at which carbonate and bicarbonate are in equilibrium. The pH decrease is apparently due to the absorption of carbon dioxide from the air as follows:

$$CO_2 + H_2O \longrightarrow H_2CO_3$$

$$Ca(OH)_2 + H_2CO_3 \longrightarrow CaCO_3\downarrow + 2H_2O$$

At pH 8.3 the ratio of free cyanide (HCN) to CN^- is about 7 to 1. A continuing decrease in pH as a result of CO_2 absorption will be relatively slow due to the formation of the bicarbonate-carbonic acid buffer system.

FIGURE 13-CONCENTRATION TRENDS IN SHALLOW BARREN BLEED HOLDING POND

(At equi-molar concentrations of H_2CO_3 and HCO_3^- the pH would be 6.5). Small changes in pH in this range, however, are reflected in large changes in the HCN/CN ratio. The gradual attainment of these low pH values and the corresponding increase in the available HCN will result in loss of cyanide to the atmosphere. Losses will be governed by Henry's Law.

Thus, after April 30, substantial volatilization of the cyanide likely occurred. Conducting the same computations as in Table 5 for the June 25th data showed that theoretically no free cyanide existed and that in fact, approximately 50% of the metals could not be complexed with cyanide.

Table 5 shows that a decrease in the concentrations of copper, nickel and zinc occurred from April 2 to April 30. It is likely that these metals precipitated as hydroxides. The slight increase in iron has no apparent explanation. Figure 14 depicts the solubility of various heavy metals as a function of pH. The minimum solubility for zinc and copper occurrs about pH 9 and increases as the pH decreases. However, even at pH 8.5, which was measured on June 25 in the pond, the zinc and copper concentrations of 1.60 and 4.39 respectively considerably exceeded the minimum solubilities indicated by Figure 14. This would suggest that these could still be precipitating as hydroxides, however, some may also still be combined with some cyanide.

Oxidation of Cyanide

From Figure 13 it can be seen that the concentration of cyanate increased from 4.1 mg/L on April 2 to a maximum of 14.3 mg/L on June 25; after which hydrolysis to ammonia and carbonate presumably occurred as the pH decreased. This increase of 10.2 mg/L of cyanate corresponds to the conversion of 6.3 mg/L of cyanide. Over the same period the cyanide concentration decreased by 58.3 mg/L from 65.3 mg/L to 7.0 mg/L. Thus the oxidation mechanism may have accounted for about 11% of the observed decrease in cyanide.

In terms of the driving force for this reaction photo redox processes are known to occur in aqueous solutions of metal cyanide complexes under illumination with ultraviolet (and sometimes, visible) lights. For example, the irradiation of ferricyanides with sunlight results in the

Figure 14 SOLUBILITY OF HEAVY METALS AS A FUNCTION OF pH

oxidation of cyanide to cyanate and the reduction of iron from the III (ferri) to the II (ferro) oxidation state. In this type of system the iron functions as a catalyst (Carey, 1981).

Biodegradation

The evidence with respect to the biodegradation of cyanide is inconclusive. Only the measurement of two parameters is germane; these are bacterial counts and dissolved oxygen. On July 2, the bacterial count was 2.0×10^5 cells/ml while at the same time the chemical data indicated that there was no free cyanide available for degradation. From July 2 to August 6, the count increased to 14×10^5 cells/ml which would tend to indicate that biodegradation of some substrate was occurring. Rather than cyanide being degraded, however, it seems more likely that the thiocyanate, which is quite biodegradable, is being degraded. Over this period, the thiocyanate decreased from 30.2 to 11.7 mg/L. The products of the reaction are carbon dioxide and ammonia, neither of which, were measured during this study. For the biodegradation of thiocyanate to occur, oxygen must be consumed. It has been estimated (IEC, 1979b) that 1.5 to 2.0 moles of molecular oxygen would be consumed per mole of thiocyanate degraded. However, in the report it was pointed out that a typical oxygen depletion in a natural stream with reaeration would likely be less than 1.0 mg/L. On August 11, the dissolved oxygen profile at two locations in the shallow pond was measured. A dissolved oxygen deficit of about 0.5 to 1.0 mg/L was noted in the water column. These data might tend to substantiate a biodegradation mechanism.

In addition, IEC (1979b), postulated that sulphuric acid could be produced by thiocyanate biodegradation. In this regard, Figure 13, it is shown that the pH of the system tends to drop slightly coincidently with the decrease in thiocyanate.

Photodecomposition

The significance of the mechanism of photo-decomposition in this study could not be assessed conclusively. Sunlight intensity was one of the meteorological parameters measured from June until early October. Correlation coefficients were calculated with the chemical parameters, pH and sunlight, however, none were found to be significant. It was hoped, based on

the literature that there might be a correlation with iron (and presumably iron cyanides). In Figure 12, it can be seen that the iron concentrations fluctuated continuously throughout the study with no discernable degradation trend although cyanate was produced perhaps as suggested in the previous section on oxidation.

Thiocyanate Precipitation

Examination of metal removal curves in Figure 13 suggests that copper may be combining with thiocyanate and precipitating in the insoluble form. There is some evidence that nickel may also be precipitating as thiocyanate. This mechanism and biodegradation may combine to account for the observed decrease in the thiocyanate concentrations. Again, however, the data are inconclusive.

Pond Geometry

As mentioned previously, the holding pond consists of two sections - a shallow section with an average depth of 3' (1 m) and an area of about 451 000 ft^2 (41 899 m^2) and a deep section with an average depth of about 20' (6.1 m) and an area of about 50 800 ft^2 (4 719 m^2). The ratio of the surface area of the shallow to the deep section is approximately 9:1. Samples were collected from the deep section of the pond from June 11. Selected parameters for the deep and shallow sections are plotted in Figure 15 (CN_T, CNO, CNS). Figure 16 (pH, temperature) and Figure 17 (Zn, Cu, Ni). In the deep pond the same phenomena appear to be occurring, however, the reaction rates appear to be slower and the constituents, with the exception of cyanide, do not appear to be removed to the same degree. These data, therefore, tend to confirm the desirability of shallow ponds for degradation.

Degradation Coefficients

Overall cyanide degradation coefficients were calculated for the shallow and deep pond data assuming a first order reaction of the form:

Figure 15 CONCENTRATION OF CN_T, CNS, CNO, SHALLOW AND DEEP SECTIONS

Figure 16 pH, TEMPERATURE, SHALLOW AND DEEP SECTIONS

3354

Figure 17 CONCENTRATION OF Cu, Ni, Zn, SHALLOW AND DEEP SECTIONS

$$C = Co\ e^{-Kt}$$

where C = CN_T concentration at time t
C_o = initial concentration of CN_T
K = degradation coefficient (t^{-1})
t = time

Data from the study, and data collected by Dome Mines during 1979 were subjected to separate calculations. The degradation coefficients obtained were:

1980 - Shallow Section
Initial Rate (First 90 days) - 0.0010 hr^{-1}
Final Rate (After 90 days) - 0.0052 hr^{-1}

1979 - Shallow Section
Initial Rate - 0.0010 hr^{-1}
Final Rate - 0.0045 hr^{-1}

1980 - Deep Section 1
Overall Rate - 0.0015 hr^{-1}

The degradation coefficients are similar for both years for the shallow section of the holding pond. The coefficient for the deep pond, as might be expected, falls between the two rates for the shallow section but is closer to the initial shallow pond rate.

Smith et al (1980) have recently published an article on the prediction of volatilization rates of volatile chemicals from natural water bodies. Using their equations and some simplifying assumptions a rate of 0.0014 to 0.0081 was calculated for stagnant ponds. The rates derived for this study fell within this range and suggest, that the observed removal of cyanide could be accounted for by volatilization.

Summary of Degradation Mechanisms

The possible degradation mechanisms as previously discussed are summarized in Table 6.

TABLE 6. SUMMARY OF DEGRADATION MECHANISMS

	Conditions	Mechanism
Stage 1 April 2 - April 30	Ice cover breaks up pH 11 - 11.5 Water Temp 2 - 5°C	CN_F volatilizes as HCN. Some Metal-Cyanide complexes dissociate CN_F - volatilizes Metals precipitated as hydroxides
Stage 2 April 30 - 25 June	Water Temp warms up to 20°C pH drops to about 8.5	CN_F volatilizes as HCN. Only complex CN remaining Some CN_T oxidized to CNO Metal cyanide complexes continue to dissociate CN_F - volatilizes Metals precipitated as hydroxides
Stage 3 June 25 to Oct	Water Temp remains in range of 17-21°C pH remains at about 8.5 slowly decreasing to 8.3 then rapidly to pH 7	No CN_F present CNO hydrolyzes to CO_2 + NH_3 CNS decreases probably as a result of precipitation with metals, probably Cu and some Ni and possibly bio-degradation Metal cyanide complexes continue to dissociate CN volatilizes as HCN Metals continue to precipitate

CONCLUSIONS

A preliminary analysis of data obtained from a 14 month study of the tailings ponds and barren bleed holding pond at Dome Mines has resulted in the following conclusions.

(1) The provision of a separate barren bleed impoundment at Dome Mines has been successful in reducing the discharge of cyanide from the tailings ponds, i.e. cyanide loadings from the

tailings ponds remain relatively constant year round, rather than the higher increasing substantially in winter loadings observed during pre-impoundment years.

(2) Natural degradation mechanisms in the barren bleed pond reduced the cyanide concentration from 68.7 to 0.08 mg/L (99.9% reduction) in the period April through September. The most important mechanism appeared to be volatilization of free cyanide. Oxidation of free cyanide to cyanate accounted for approximately 11% of the total cyanide conversion. The relative roles of photodecomposition and biodegradation could not be delineated.

(3) The tailings pond system at Dome Mines achieved average cyanide, copper, nickel, zinc and iron removals of 65, 33, 19, 77 and 0%, respectively.

(4) An important sbustantive data base has been developed on the operation of a tailings pond system and a barren bleed holding pond at a Canadian gold mine.

RECOMMENDATIONS

Although a substantive data base has been developed on natural degradation, the operative mechanisms and the implications for design purposes have not been sufficiently delineated.

Therefore, it is recommended that the following be undertaken:

- Completion of the analysis of the available data.
- Conduct further full scale studies to confirm the results of this study and provide data on additional parameters eg. NH_3, alkalinity
- Conduct appropriate "bench scale" studies on simulated effluents in an attempt to better identify possible degradation mechanisms and to assess the applicability of the "degradation process" to effluent from other mines
- Develop suitable design criteria in order that "natural degradation" may be used as an alternative technology or in combination with other technologies for cyanide and metal reduction

GIANT YELLOWKNIFE MINES, NWT

Giant Yellowknife Mines is the subject of a detailed trip report in Appendix I.

The Giant Mine is located just south of the Arctic Circle on the north shore of the Great Slave Lake. In this part of the world there is no shortage of fresh water although its use is regulated by the Northwest Territory Water Board which allows a maximum annual consumption of 1,950,000 m^3 per year for the 325,000 tons mined and milled annually. This works out to 6.6 m^3 water per ton ore milled which reflects the plentiful availability of water.

Giant cyanide leaches a calcined flotation concentrate. The calcine is water washed before cyanidation. All effluents and tailings are commingled and pumped to a common tailings dam from which the decant is treated to remove cyanide and metals by alkaline chlorination and to remove arsenic by addition of ferrous sulfate and decanting.

The long frozen winters require that effluent be treated during the summer months only and accumulated in the tailings dam during winter. This requires a tailings dam with a large capacity and an effluent treatment plant capable of treating the whole year's liquid effluent in five to six months.

Although only the calcine and Cottrell precipitator dust from roasting are cyanided, i.e., only about 110 tons per day of material, the complete effluent from the tailings dam must be treated due to historical commingling. This arrangement does benefit from some natural degradation in summer.

If one were starting from scratch, undoubtably this operation would use roaster gas to detoxify just the cyanided calcine tailings which could be disposed of separately. Since these contain some residual undissolved gold, they would also represent a potential future resource if they were not commingled.

Seepage into the mine from the tailings decant pond downstream from the tailings pond resulted in a low level of cyanide in water pumped from the mine. Since the new cyanide destruction plant was installed to treat tailings decant ahead of this pond, cyanide has no longer been detected in minewater.

Giant Yellowknife recovers some incremental gold from treated effluent after decantation. Possibly residual cyanide contained in the commingled tailings helps in the leaching of some of this gold over a long period of time. It is not clear whether this opportunity would be lost through segregating the tailings as mentioned above.

Giant Yellowknife saves a considerable additional water treatment expense through careful housekeeping to keep arsenic flue dusts away from water.

Water management at Giant Yellowknife Mines is discussed in greater detail in a trip report in Appendix I.

CON MINE, YELLOWKNIFE, NWT

The Con Mine used to treat a refractory arsenopyrite gold ore which required roasting. For the last decade or more the mill has been treating a non-refractory gold ore by direct cyanidation. However, two sludge ponds containing arsenic flue dusts from the old, and now dismantled Edwards roaster remain and presented a threat of contaminating effluents and groundwater that ultimately could find its way to Great Slave Lake.

The Con Mine is also the subject of a trip report in Appendix I, and only a few features are mentioned here.

First, Rather than deal with the arsenic ponds as an environmental reclamation project, Cominco has developed a process and installed a $13 million plant to recover arsenic and a recoverable gold residue from the sludges.

Second, The tailings dam at the Con Mine is very large and shallow. Tailings are treated before leaving the tailings line by injecting excess lime, sodium sulfide and ferrous sulfate to precipitate most of the cyanide. Additional ferrous sulfate is broadcast over the decanted solution pond to further reduce cyanide and arsenic. Natural degradation does the rest.

Third, The water use permit allows the Con Mine also to use 1,950,000 m^3 water per year which reflects the abundant supply available.

Fourth, Like the Giant Yellowknife Mine the total volume of tailings are treated to remove cyanide and metals. Unlike Giant Yellowknife, the Con Mine process arrangement allows no opportunity for segregating various tailings streams. All the ore is cyanide-leached.

Finally, Performance data on the cyanide and metal removal performance of the Cominco patented cyanide removal process employed is impressive. Details of the $FeSO_4$ plus Na_2S cyanide destruction patent are provided in Chapter 10 on cyanide destruction.

No effluent solutions are recycled to the Con Mine, it is all treated and discharged.

The cyanide levels in effluent allowed by Cominco's Con Mine operating permit are relatively lenient at 1.5 mg/l CN_T maximum average and 3.0 mg/l maximum in any grab sample, compared with some other parts of the world.

More information about the cyanide removal and arsenic recovery processes can be requested from:

ECHO BAY MINES, LUPIN PROJECT

The Lupin Project treating 1000 tpd ore is located about 450 miles north of Yellowknife NWT about 125 miles north of the nearest tree. Managing water at an operation in such a cold climate presents a challenge or two. This property was not visited but some interesting aspects relating to water management were referred to by KARKLIN (1984). The ore characteristics require a unique processing step which affects water needs too.

The Lupin orebody is classified as a stratabound iron sulfide deposit. Gold particles average about five microns in size and are found in the iron rich sulfide layer bounded by quartzites. Gold occurs predominantly as microscopic grains associated with arsenopyrite and pyrrhotite. Other minerals in the ore include chalcopyrite, actinolite, silver, pyrite and minor rare earths.

AERATION

Because of the large amount of soluble sulfides and ferrous iron the ore after grinding to 90% minus 200 mesh is subjected to three stages of aeration at elevated pH using lime.

Three preaeration tanks each 24 ft Ø X 26 ft high are used to aerate cyclone overflow from the grinding circuit directly in 32% solids. After aeration the pulp is thickened to about 60% solids in a single 40' thickener and then diluted to 45% solids using barrens. One of the three aeration tanks has in the meantime been converted into a recycled water tank as part of an expansion program.

Lupin ore contains 18.8% iron, 3.8% sulfur and 3.6% arsenic, and after aeration the following assays in the thickener overflow are achieved:

S^{-2} - 2 ppm

$S_2O_3^{-2}$ - 4 ppm

SO_4^{-2} - 30 ppm

This step is necessary to maintain recovery and to conserve reagents. Unoxidized sulfide would preferentially consume cyanide and oxygen which would slow the dissolution of gold.

The thickener overflow is recycled to the grinding circuit. Presumably almost all the soluble iron that came with the oxidized sulfide will be in the ferric hydroxide state in

the aerated pulp. It remains to determine what effect this iron hydroxide has on the process. Is it cyanide soluble? If so, it would undoubtedly tie up a considerable amount of cyanide as ferricyanide complex.

The effectiveness of the preaeration step is demonstrated by the fact that even with recycle of the thickener overflow from the preaeration thickener, and recycle of barrens only 1.0 lb NaCN/t, .20 lbs $Ca(OH)_2$ and 0.65 lbs lead nitrate are required to achieve 90% leach recovery of gold. Level of arsenic in the leach solutions are kept down by maintaining a "low" pH at 10.3.

1,000 tpd ore yields 2800 m^3/d solution after filtration and washing. Much of which is recirculated as barrens.

Water brought into the plant must be heated so as much water as possible is recycled in the plant until fouling occurs, then the minimum amount is bled. In this sense water management also overlaps into energy management in this cold climate.

Tailings are pumped five kilometers over frozen tundra down to minus 60°C across two valleys to the disposal site. This requires a special pump arrangement described by KARKLIN (1984).

The tailings line is constructed of 6 inch, schedule 40 steel with flanged connections. The entire line has two inches of urethane foam insulation extruded around it, which is further protected with a 24 gauge galvanized metal jacket. The entire line is heat traced.

To enable line dumping in the event of power failure, dump valves are located at each of the two low points along the line. Vacuum breakers are fitted at the high points of the line.

The tailings pond is 250 acres in size and it is relatively shallow with low dam walls. Natural degradation of cyanide is found to be effective in such a large pond. Treatment of the final pond effluent is currently under study. The pond is designed to allow five years of retention prior to any effluent discharge. During the five year interval a program is underway to demonstrate that an environmentally acceptable effluent, as dictated by the terms of their water license, can be discharged. Two programs are currently underway. First is a detailed analysis of the aquatic environment that will receive the effluents. The second is a testing of various systems to determine the most effective process for treatment of pond effluents.

Washed filtercake is repulped with recycled water including high iron thickener overflow from the aeration step which presumably will tie up much of the cyanide as ferricyanide complex.

PREAERATION

KARKLIN

Additional information on the special water management considerations required for a mine-mill in such a cold climate can be obtained from:

Graham Karklin

By 1985, the natural degradation phenomenon had been studied in great detail at the Lupin project. In winter, all effluent in the tailings pond is frozen solid. In spring, after the ice breakup, cyanide levels increase steadily in the decant solution until around mid-August when suddenly there is a dramatic reduction in cyanide levels. The steady wind and 24-hour sunshine over the shallow pond with a large surface area is ideal for natural degradation. It has not yet been firmly established whether the mechanism is CO_2 absorption to volatilize cyanide or a biological removal process of some sort, or both.

It is believed that ECHO BAY MINES plans to divide their pond into two areas; one for primary treatment in which ferrous sulfate will be added to precipitate arsenic, and a second polishing pond. It appears that the Lupin project will provide the first case study of a completely successful natural cyanide degradation demonstration in arctic conditions. To date, it appears that this operation will easily meet the North West Territories cyanide limit in their final effluent when their existing pond has to discharge effluent in a year or two. LAC MINERALS - LA MINE DOYON

La Mine Doyon, a joint venture between LAC MINERALS LTD. AND SOQUEM, the Quebec Government owned mining company, is located in Quebec. This account is based on sketchy information but indicates a potentially useful way of enhancing natural degradation.

One of the challenges faced at La Mine Doyon on account of the cold climate is dust control. The ore is high in silica and dust could be hazardous to operators. Because of the very cold climate air must be preheated before it is brought into the mill. Also, for energy conservation reasons, the mill is well insulated and carefully winterized. Consequently the exchange of air required for dust removal is an energy drain. The La Mine Doyon mill has 30,000 cfm dust collecting capacity which the company would like to double.

At La Mine Doyon ore is ground and leached in cyanide then recovered by Merrill-Crowe. Barrens are recycled so most of the cyanide stays in the gold circuit except that which is not washed from the tails in the solid-liquid separation stage. Tailings are pumped to a pond from which the decant is discharged as a final effluent into Ruisseau Lac Bellot where it is diluted. This discharge of effluent resulted in an increase in cyanide and copper values in Lac Bellot. The discharge had to discontinued while ways cyanide destruction techniques were researched.

La Mine Doyon testwork, for which at this time only qualitative data were made available to this investigation, indicate that through aeration, and particularly through aeration and nutrient addition, natural degradation can be greatly enhanced.

No details were obtained on the nature of the nutrients nor on how the concept will be applied in practice, or whether it is temperature dependent i.e., seasonal in application. This work was still in infancy but appears promising.

More information on La Mine Doyon and the aeration-nutrient addition tests could possibly be obtained from Lac Minerals, bearing in mind that details may be considered proprietory until a process has been developed and tested.

This marsh concept may prove valuable in developing an enhanced natural biological cyanide degradation system which would also help polish precipitated metals from effluents.

UNITED STATES

Water management for US gold and silver mining and milling operations focuses on each of the main aspects of water management, depending on the site specific nature of the operations:

Removal of suspended solids: Placer Mines in Idaho, Colorado, Alaska, California, etc.

Shortage of water and need to conserve: Heap Leaching operations in the Mojave, in parts of the Colorado plateau, and Nevada.

Removal of cyanide and metals from effluents: Homestake Mining Company, Lead, SD; Noranda Grey Eagle Mines, Inc., California Superior Mines, Inc., Stibnite, Idaho.

High TDS in available water: American Mining Co., Amboy, CA

Containment of effluents, zero discharge: Pinson Mining Co.; Freeport Gold Company; Cortez Gold Mines, Carlin Gold Mining Co.; Candaleria Silver Mine; McLaughlin project, California, and many others.

WATER MANAGEMENT FOR PLACER OPERATIONS

Placer gold recovery varies in size from very large dredging operations processing up to thousands of tons per hour down to one man part-time operations using sluices of all kinds.

Placer operations are frequently located in or alongside creeks and streams, for that is where most placer deposits were formed in the first place. Gravity concentration techniques require a lot of water and the stream is usually the best and most convenient source of the operation's water needs.

Sometimes there is not enough water in the stream and so water must be recovered and recycled. Other times water is drained from the placer tails and discharged back into the creek. In both cases suspended solids represent a problem. Recycled water builds up suspended solids, including clays and root particles, etc. until it may interfere with the recovery process - especially with some of the more sophisticated enhanced gravity centrifugal concentrating devices such as the Knelson Bowl Concentrator.

In the USA the Surface Mining Control Act SCMRA directly affects placer mining operations. It requires, among other things, that seepage or drainage from the operation must be treated to reduce suspended solids and that this water may not enter a natural stream unless it meets a series of standards. For most states these regulations require that suspended solids be reduced to below 35 mg/l (daily average) and below .70 mg/l for a 30-day sample.

The most convenient way to meet the suspended solids (TSS) criteria is to provide sedimentation ponds as needed to remove particulate matter. These ponds, however, often have a limited size and lifespan dictated by topography, the scope of the mining or processing operation and the quality of sediment in the water to be treated and discharged.

If the collected water has a higher SS than can be directly discharged, and if the flow rate is too high for a satisfactory detention and settling time, the mine or plant operator has to make some decisions about the ponds before a situation develops that could close down his operation or result in a fine. There are two main options:

- To build additional ponds.
- To install a flocculant treatment system to increase settling rates.

Building additional ponds may not be possible because of topographical constraints and may also be expensive. Addition of a suitable chemical flocculating agent to agglomerate fine particles into larger ones and increase their settling rate also results in improved sludge compaction.

The technology needed to set up a flocculant treatment system for a settling pond involves the need to know the flow rate, correct flocculant type and the correct dosage. Such systems involve metering pumps, mixing devices to prepare polymer solutions, etc. and may also therefore require a power supply and a source of makeup water at the site, as well as a suitable mixing zone where the flocculant and stream come in contact before dispersing into the pond. This can be both impractical and expensive, especially for a small scale mining operation. Time requirements to monitor and maintain the system, adjust dosage levels, replenish the polymer supply etc. can be excessive.

An innovative new flocculant polymer in gel form meets the following advantageous criteria:

- Does not require electricity, piping, pumps, tanks or other preparation and delivery equipment.
- Functions unattended for days at a time with minimal operator attention.
- Responds to changes in flow rates to keep dosages relatively constant.
- Shows visually when replenishment is needed.
- Is in a form that can be carried by hand to unaccessible locations.

The Hercofloc logs are available in a range of ionic functionalities and can be selected to match the needs of each system. Each gel log weighs 40 lbs and measures 18 inches long by 9 inches in diameter.

The application of Hercofloc logs mainly in remote coal mining operations was described by MOORE (1982) and these should be ideally suited for the medium and small scale placer miner and where suspended solids in recycled water interfere with the performance of equipment such as the Knelson Bowl Concentrator. HEAP LEACHING AND MILLING

The industry is distributed mainly through the western states where the climate ranges from extremely arid - e.g., in the Mojave Desert, to arid with cold winters as in the Nevada highlands to warm as in Arizona, and wet with snowbound winters in Idaho.

Although there are currently no cyanide limits under the Federal RCRA regulations governing solid waste disposal at this time, it is expected that these will ultimately be developed under a new set of regulations designed to protect groundwater quality. Regulations do limit cyanide levels in effluents discharged to surface waters, however.

Incentives to practice water management and to apply water treatment at gold and silver mining and milling operations vary from the need to recycle every possible drop of water due to lack of availability, to the economic advantages of reagent savings through recycling to the need to comply with federal and/or state regulations. In addition some operators must make do with high TDS or hard water that must be treated before use.

Regulations that have an impact on water management range from the Federal "Clean Water Act" of 1977 with its BCT, BPT, BAT and NSPS regulations; the RCRA law and associated regulations governing solid waste disposal (applicability of which to mine and mill waste has been temporarily suspended). Discharge to surface waters is regulated by the EPA or the agreement states under NPDES regulations.

The trend is increasingly to transfer responsibility for regulating mining industry effluents and waste disposal to state governments as long as they are at least as stringent in their regulations and their enforcement as the Federal regulations. This has added greatly to the confusion and complication of securing permits for mining operations in many states because the state and local regulators often are not experienced in mining and metallurgical wastes and tend more often than not to try to get "unrealistic" regulations passed into state law which would make it impossible to mine or mill ore without becoming a criminal in the process. California is a trendsetting state and how this issue is resolved there - especially the rules dealing with "hazardous waste" disposal will have an influence on operations in many additional states - such an influence can already be seen in Washington, Montana, South Dakota, and even as far afield as Pennsylvania.

The problem is that different regulations are now emerging in each state and these are extremely complex. It would take a full time legal staff to keep up with the regulatory developments and since few of the regulators, the law makers nor the lawyers hired by the mining industry to fight their case have experience in mining and mineral processing, the whole ball of semantics wax seems to have got somewhat out of hand. In addition to the complexity of state regulations, the Federal CERCLA 'Superfund' regulations and the emerging EPA groundwater protection regulations are expected to have potentially serious consequences.

Examples of the severity and complexity of some of these regulations are provided in Chapter 7 on Regulations and Regulatory Trends. These include an excerpt from a California Regional Water Quality Control Board permit issued to ASARCO for the Waterloo silver operation in that state, and an NPDES permit issued to Homestake Mining Company

House panel probes wilderness mines

By Mike Stewart
The Star-News

A congressional inquiry into federal management of Thunder Mountain mining activities has been initiated, according to a congressional staff member.

The probe has been started by Rep. John Sieberling, D-Ohio, chairman of the House Subcommittee on Public Lands, according to Andy Wiessner, counsel for the subcommittee.

"We sent a letter to the Forest Service asking them about what happened there," Wiessner said.

While the inquiry is aimed at the events surrounding past spills of mining tailings into creeks in the area, it also addresses the broader issue of management policies toward mining operations located on lands adjacent to wilderness, Weissner said.

Sherry Wagner, public information officer for the Payette National Forest, said Friday that the forest had received the inquiry, but that it did not specifically address last fall's spill at the Golden Reef mine.

Rather, it requested general policy information on how such operations are managed from the federal government's point of view.

Information to be included in the response has been forwarded to Forest Service headquarters in Washington, D.C.

The Golden Reef spill took place last September or October, when several tons of sludge scooped out of settling ponds at the mine slid into Mule and Monumental creeks.

The sludge wiped out salmon and steelhead spawning beds in the creeks, according to Idaho Department of Fish and Game officials.

A settlement among Golden Reef operators, the Idaho Departments of Health and Welfare and the Idaho Department of Lands followed. The mine's operators paid a $5,000 fine and $20,000 for damage done to the streams.

While Sieberling's inquiry is directed at the Forest Service, that agency, with the state lands and health and welfare departments, are only three of the half-dozen or so agencies that have jurisdiction over different aspects of Thunder Mountain mining operations.

That fact helped foster claims made at the time by the Idaho Conservation League. The ICL said said government agencies were not watching the situation closely enough and were not being harsh enough in handing out penalties for violations.

Later, however, the ICL supported the settlement between the state of Idaho and the mine operators.

In criticizing the way the situation was handled, Wiessner said Sieberling was most interested in what was being done to prevent a repeat occurance.

for the McLaughlin project. Usually owners of a new mine and mill must apply for, negotiate and comply with numerous permits from various bureaucratic authorities. GUINIVERE (1984) pointed out that Homestake Mining Company had to apply for 281 permits in all for the McLaughlin project in California but not all of these related to water and effluents. The situation was complicated by the fact that the operation covering a 25 mile long project site extends into three counties each with their own regulatory authorities. GUINIVERE (1984) estimated that the overall environmental and permitting costs for the $250 million project which took four years to permit amounted to $22 million in all including:

$6 million:	EIR preparation and environmental backup.
$5 million:	Dams for sediment control.
$11 million:	Special design features, dust collection and runoff control during construction and operation.
$22 million:	Total

The McLaughlin Project is described in summary form in Appendix I based on published information. FERGUSON, et al. (1983) presented an interesting paper on how the water balance for this new operation was modelled. Their paper is inserted in Chapter 10.

Inserted below is an estimate by NORANDA of the additional costs incurred at the NORANDA GREY EAGLE MINES INC. 500 tpd operation in California to correct an unexpected minor cyanide seepage from their tailings pond which was in fact found to have resulted in negligible, if any, damage to the environment. The mitigating measures were estimated to cost an additional $10,498,000 on top of an original capital cost for the whole project of $20 million. The $10.5 million includes additional operating costs for the additional facilities and a contingency of 25%. This works out to an approximate cost of $11.66 per ton of ore for the remaining life of the mine.

Liquid effluents discharged to surface waters are governed by NPDES permit requirements.

Permits for all the gold and silver cyanidation plants in the USA located where it is climatically possible call for "zero discharge" of effluents. This is readily achievable in the low rainfall areas of the country where most of the gold mining operations are located.

Federal RCRA solid waste disposal regulations do not apply to mining and milling wastes for the time being, but the industrial states, led by California, apply their own hazardous waste discharge regulations to mine wasterock and mill tailings disposal.

8 July 1983

INFORMATION MEMORANDUM

FROM: M. Wasserlauf

TO: S. Wulf

SUBJECT: NORANDA GREY EAGLE MINE - PROJECT N-8321-3B - DESTRUCTION OF CN IN TAILINGS SLURRY - METALS STABILITY

SUMMARY

Leaching tests were conducted on Grey Eagle tailings after treatment for CN removal by SO_2 oxidation. Results of these tests indicate metal (Cu, Zn, Fe) levels of < 1 mg/L at pH 5.5. At a pH of 4.5, levels were significantly higher, with Cu and Zn concentrations ranging from 2.5 to 22.3 mg/L.

LEACHING TESTS

Grey Eagle tailings were treated for CN removal by SO_2 oxidation. Results of these studies were reported previously([1]). Metals anlaysis were subsequently carried out on filtered tailings decant before and after CN detoxification studies. The results were as follows:

	Sample	Cu (mg/L)	Zn (mg/L)	Fe (mg/L)
	Mill Tails Decant	228.6	11.35	5.4
Tails Decant	After Alkaline Chlorination	0.4	0.27	6.1
Tails Decant	After SO_2 Oxidation	3.1	0.11	0.5

The tailings after CN removal were then subjected to leaching tests. Samples of tailings solids (see Table 1) were placed in Erlenmeyer flasks, with volume then adjusted to 250 ml with distilled water. Sulphuric acid (1N) was added to adjust the pH to 4.5, and 5.5, and the flasks were placed in a Burrell Wrist Action shaker and agitated at 100 movements/minute for a 24-h period. The pH was monitored, and adjusted to the initial values continuously during the test. Subsequently, the liquid was filtered, and analyzed for Cu, Zn and Fe.

RESULTS

The results of the leaching studies are summarized in Table 1. As indicated, Cu and Zn levels were significantly higher at pH 4.5 levels than at pH 5.5 levels. Iron levels did not change.

NORANDA GREY EAGLE MINES

ESTIMATED COSTS OF REMEDIAL MEASURES

(1983 $)

	Capital	Operating	Total
1. Construct tailings dam third stage one year early $2,093,000 @ 10%	$ 200,000	$ -	$ 200,000
2. Flow reduction system	300,000	60,000	360,000*
3. New pumpback system	275,000	60,000	335,000*
4. Modification to water treatment plant	125,000	-	125,000*
5. Construction of toe-of-dam plant	1,900,000	4,500,000	6,400,000*
6. Sealing mine adit	75,000	-	75,000*
7. Water treatment costs due to pumpback system	-	200,000	200,000
8. Production interruption to install temporary pumpback	-	400,000	400,000
9. Engineering and research (Task force, consultants, and legal)	600,000	-	600,000
Sub-total	$3,475,000	$5,220,000	$8,695,000
*Contingency 25% of $7,210,000	650,000	1,153,000	1,803,000
Total	$4,125,000	$6,373,000	$10,498,000

Note: A. These costs exclude interest charges on the additional capital required to complete the program.

B. Approximate cost per ton: $\frac{\$10,498,000}{900,000 \text{ tons}} = \$11.66/\text{ton}$

There are no current Federal regulations governing cyanide limits in effluents or tailings, although heavy metals are regulated at low levels which indirectly regulate cyanide which must be removed to achieve the base metal limits. NPDES permits for effluent discharge, however include very strict cyanide limits in the few cases where they are granted for gold cyanidation effluents.

The Homestake Mine at Lead is of the few operations which is permitted to discharge an effluent subject to meeting extremely strict effluent limits for cyanide, metals, and ammonia as shown in the table inserted below. Despite enormous expense and effort these limits have yet to be met, although the performance of their new biological cyanide destruction plant using innovative technology will soon be known. Homestake Mining Co. has developed a new biological treatment process for cyanide destruction and metal removal. This is expected to be the "state of the art" in cyanide destruction where it is applicable. It is believed that an agreement has been reached with regulatory agencies whereby the final effluent permit requirements at this site will be tailored, if necessary, to the performance achievable provided in-situ bioassay shows that its effluent is environmentally compatible.

Homestake Mining Company discharges a combination of minewater and mill tailings decant effluent which requires a very expensive treatment facility to even approach the required effluent limits. Their plant and the new technology is briefly discussed in the chapter on cyanide destruction.

Duval Corporation's Battle Mountain operations which recover gold from an ore with relatively high levels of cyanide-soluble copper uses alkaline chlorination to decompose cyanide and precipitate base metals before discharging the tailings via a series of drop-boxes to the desert valley below the mine.

Some water management practices observed at US gold and silver recovery operations are summarized below.

HEAP LEACHING

Heap leaching of low grade oxidized gold and silver ores originated as a practice in Nevada. Agglomeration of fines requires that the ore not contain more than about 11% moisture which means that it must be pretty dry.

CANDALARIA SILVER HEAP LEACH, NERCO METALS, HAWTHORNE, NV

The Candalaria Partners operation was described by VAN ARSDALE (1984). 7500 t/d (metric) of ore are placed on the heaps which are irrigated with a 1.5 Kg NaCN/ton

solution at a rate of 14,500 t/d solution flow through the plant, or 0.012 m^3/h per m^2 (0.005 gpm/ft^2) through sprinklers.

In the fall, a wintertime leach area is constructed of new ore. This is fitted with 100 mm (4 inch) diameter perforated pipes on 9 m (30 ft) centers buried about 0.9 m (3 ft) into the ore. During freezing conditions solution is brought to these pipes by an above ground system similar to the normal spray system except that flexible rubber hose is connected from the spray points to the underground pipe. This permits a continuation of production at a reduced rate. Due to the solution flow configuration only 65-70% of normal production is maintained during extended periods of cold weather.

Candalaria uses NaOH for pH control.

Net water consumption is reported by VAN ARSDALE (1984 personal communication) to be 200 US gpm which works out to 1090 m^3/d of solution or 0.145 m^3 water per ton ore treated which makes this an extremely water efficient operation.

There is no barren bleed or effluent discharge of any sort. Heap pads are clay lined - and the drainage ditches and ponds are hypalon lined so seepage will be minimal. The operation is designed and operated for zero discharge.

The water source is 4.5 miles from the plant and it contains some carbonates.

Drew Chemicals Millsperse 802 is applied as a scale inhibitor at the rate of 50cc per minute to the barren pond to minimize scale formation in the heaps.

PINSON MINING COMPANY, WINNEMUCCA, NEVADA

Most Nevada heap leaching operations shut down for several months during the winter when the heaps freeze over.

PINSON MINING COMPANY operates a conventional CIP plant and, in addition, it heap leaches low-grade ore. What is most interesting is that they operate the heaps right through the winter, allowing a 3-4 foot ice layer to build up on top of the heaps. The ice is not a continuous sheet and allows the cyanide to reach the heap material and percolate through it.

To apply spray solution through the thick ice capping, sprinklers are mounted on 4' vertical stems so that the sprays can work over the ice.

Remarkably, cyanide does not seem to be locked up in the ice, possibly because some form of freeze-desalination is at work.

During the frozen months, the solution application rate is cut back slightly, and the production rate of gold from the heaps is slower than in summer. The important point is that cash flow from the heaps does not stop.

Because of the large inventory of water tied up in the ice cap, provision must be made to contain it during the spring melt. This means installing an adequate pond storage capacity. PINSON MINING COMPANY carefully computes their water balance and inventory.

PINSON MINING COMPANY
Post Office Box 192
Winnemucca, NV 89445
(702) 623-5036
R. Bruce Thorndycraft

AMERICAN MINING COMPANY, AMBOY, CALIFORNIA

AMERICAN MINING COMPANY operates a heap leaching venture in the Mojave Desert. Available water in this region is very high in dissolved solids, and this has brought most attempts at heap leaching in the area to their knees.

AMERICAN MINING COMPANY, however, is able to operate profitably using a water which is saturated in calcium chloride--to the extent that the salt crystallizes out in the drainage ditches. Carbon columns are used for gold recovery, but it has not been revealed how they keep the heaps and carbon beds from cementing up or the carbon from fouling. More information could be requested from:

CORTEZ GOLD MINE, CORTEZ, NV

This operation receives 5" of rain per year with an additional 9" per year rain equivalent as snow and 60" per year evaporation.

The operations treats a combined 2,000 stpd by a carbon-in-leach and 4,000,000 stpa by heap leaching.

USE OF PRESSURE/VACUUM LYSIMETERS FOR OPERATIONAL AND ENVIRONMENTAL MONITORING AT HEAP LEACH MINING FACILITIES

With the growing interest in heap leach techniques to recover precious metals from low grade ores, the monitoring of leach solution flow balance is a primary concern for both production efficiency and environmental protection. When leaching marginal grade ores, every drop of leachate becomes as precious as the metals themselves. In many cases, a loss of five or ten percent of leach solution through liner leaks can be the difference between success and failure. Leaks into the subsurface can result in extensive liabilities such as contamination of soils and ground and surface waters. Clean-up costs can be quite significant and future mining development may be prevented by concerned government regulatory personnel.

Envirologic Services International (ESI) has recently adapted an agricultural soil water monitoring technique as a method to detect the loss of leach solution. The pressure/vacuum lysimeter has proven to be a cost-effective monitoring tool that satisfies both leachate flow balance and environmental protection concerns. With proper planning, the installation of lysimeter units beneath the heap leach pads and solution ponds can give quick, reliable leakage detection. A lysimeter under a leach pad can detect a leak within several days or weeks, depend-

DIAGRAM OF PRESSURE-VACUUM LYSIMETER INSTALLATION

TYPICAL LYSIMETER INSTALLATION AT A HEAP LEACH MINING OPERATION

ing on the location and magnitude of the leak. The same leak may take months or years to be detected by perimeter monitor wells, and then only after contamination of vadose and ground water has occurred.

For maximum reliability and minimum cost, the installation of the lysimeters and their sample lines should be completed before the final emplacement of clay and synthetic liners. In most cases, the installations are shallow, three to five feet, and easily completed in a few hours. Sample lines are quickly laid in trenches dug by trenching machines. The lines can be covered with a sand backfill or run through one inch conduit prior to backfill. Permanent sample stations can then be constructed away from the leach pads, ponds and traffic right-of-ways.

Details on the installation and use of pressure/vacuum lysimeters were provided in a paper titled "Several Uses of Pressure/Vacuum Lysimeters at Mining Facilities and Hazardous Waste Sites" by William R. Bond and Jim V. Rouse, of ESI, presented at the October 1984 SME meeting in Denver. (Copies available upon request.) The paper stressed that pressure/vacuum lysimeter units are a cost effective, simple monitoring tool to be used for operational control as well as regulatory monitoring. At marginally operating heap leach mining facilities, lysimeter vadose monitoring can spell the difference between success and failure in today's unsettled metals market.

Envirologic Services International (ESI) is a division of J.H. Kleinfelder & Associates, a California-based geotechnical and environmental engineering firm specializing in hazardous wastes investigations, and materials and soils engineering. ESI provides environmental consulting services to the mining and minerals industries in the areas of baseline and site monitoring, pollution control, and geohydrologic/geochemical investigations for hazardous waste sites.

Average net new water intake is 120 US gpm from wells at a pumping cost of $5000/year. The wells are located at the plantsite. This means that an average of 3142 stpd or 2856 t/d ore are processed using 655 m^3/d net fresh water or 0.23 m^3 water per ton ore net use. 500 gpm solution decant is recycled to the process from the mill tailings, and an average of less than 5 gpm barrens is bled to maintain a solution balance.

The operation is designed and run for zero discharge so no effluent treatment is required.

Because reclaim solution containing cyanide is used in the grinding circuit and because the ore is mildly preg-robbing Cortez is testing the use of NaOCl to destroy cyanide in the tailings reclaim solution. If installed, the cyanide decomposition step would cost $0.08 - $0.10 per ton ore.

Anti-scaling reagent Drew Chemicals, Millperse 802 is added at the rate of 2-5 ppm to the carbon elution circuit.

FREEPORT GOLD COMPANY

The Jerritt Canyon Mill near Elko, Nevada treats 3500 st/d (1,300,000 stpa) ore by carbon-in-pulp. The refractory preg robbing ore is first treated with chlorine and then leached in cyanide.

No water is recycled from the tailings dam and water costs $180,000 - $200,000 per year at a unit cost of $0.33/1000 gallons. Water is pumped from wells 2 miles from the plant, i.e. 600,000,000 US gpa = 2,272,000 m^3/yr which works out to a total net usage of 1.75 m^3 per ton ore.

Rainfall amounts to 12 inches per year with an estimated additional 12" as snowfall precipitation, and evaporation is 40" per year.

A barren bleed of 9,000 US gallons/day (34 m^3/d) is discharged 5 days per week from the eluate to bleed zinc.

Although no tailings decant solution is recycled to the plant, 1200 US gpm is pumped through carbon columns to reclaim some incremental gold.

The mill-tailings system is operated for zero discharge which has been achieved from 1981 to 1984. Since fresh water is used with no recycle, no anti-scaling reagents are needed or used.

Tailings decant solution is not recycled due to the high chloride levels.

GETTY MERCUR MINES, TOOELE, UT

The Mercur Mine was first worked one hundred years ago. The ore is refractory because of its preg-robbing characteristics. It also contains cyanide soluble thallium.

The Getty Mercur Mine's operation uses a carbon in leach process to overcome the preg robbing-nature of the ore. However, when water is recycled from the tailings pond, it contains residual cyanide which, if used in the ball mill, would start leaching gold which, in turn, would be robbed by carbonaceous species in the ore. Consequently, it is necessary to remove cyanide from the recycled tailings solution. This is achieved by reacting the solution with sodium hypochlorite before it is returned to the mill. The Getty Mercur Mine also is a zero discharge operation. In recycling solutions, cyanide is destroyed for the reason given. Thallium is removed from the system by washing it from the activated carbon used to recover gold, which is achieved with cold nitric acid. The acid washwater is neutralized and Na_2S added to make sure all thallium is precipitated. The precipitate is disposed of in the tailings pond.

This operation also has installed bentonite stabilized sand linings under its tailings pond which are super-impermeable. The Getty Mercur mill is described by WICKS and BREWER (1984). The authors can be reached as follows:

RECOVERY OF INCREMENTAL RESOURCE VALUES FROM EFFLUENTS

During the course of this investigation, several examples of resource recovery from effluent streams were encountered. In some cases, the recovery process was installed solely with the motive of making a profit from the sale of the recovered resource--e.g., gold recovery from the effluent from gold mine-mills using activated carbon or the recovery of copper by SX from El Teniente's copper mining effluents in Peru. Another example is the recovery of uranium fr[illegible]water.

In other cases, metal values are recovered in sludges as a result of the treatment of effluents to meet discharge water quality limits, and the values in these sludges are recycled to metal recovery operations as a means first of gaining a credit for the metal values but, often more importantly, as the safest way of disposing of the sludges. Examples of this type of operation are COMINCO LTD., Trail, B.C., NORANDA at their Mattabi Division, Ontario, and several others.

In still other cases, resource values are recovered, but their value or the cost of recovering the values and possible metallurgical problems that would be introduced as a result of returning the precipitate sludges to the primary metal recovery process do not work out to be economically attractive--as, for example, has been found at AMAX's Climax Molybdenum operations in Colorado where molybdenum can be recovered in their water treatment plant by ion exchange.

Some examples of gold, uranium, and other base metal recovery are summarized below. The first of these is a purely speculative concept still at this stage and has not yet been studied in detail. It is a "long shot" but deserves attention because it seeks to recovery salable energy in transportable form from acid mine drainage and pyrite. Acid mine drainage and sulfides in tailings that cause it are the most serious causes of pollution that will seriously affect the economics of the mining and milling industry in some parts of the world where tailings impoundments and effluent treatment plants will require "perpetual" maintenance. Therefore, any concept that has even a remote chance of making a salable product to generate revenues that could offset the cost of tailings management and treatment of acid mine drainage has a very important possible impact. Therefore, although it is the least defined or developed, the concept proposed by Professor Al Stiller of the University of West Virginia deserves to be first on the list.

1. Hydrogen from Acid Mine Drainage and Pyrite: Concept

Professor Albert Stiller has proposed for further testing and development the concept of using acid mine water at pH 2, pyrite, and scrap iron as components of a galvanic cell that would generate hydrogen which would be recovered as a salable fuel resource.

PROFESSOR AL STILLER
Dept. of Chemical Engineering
University of West Virginia
Morgantown, WV
(304) 293-5398

Of all the resource recovery examples discussed here, this one is the least developed. Granular or briquetted pyrite would be immersed in AMD as one electrode and, when brought in electrical contact with shredded scrap iron as the other electrode, hydrogen would be generated. A process to collect this hydrogen has yet to be developed. Possibly the use of sonic resonance as proposed by Al Bodine of California would help release hydrogen bubbles from the pyrite surface, thereby keeping its surface more

reactive. Randol International Ltd. has no data on the possible economics or practicality of this process still raw concept.

2. Sulfur from Acid Mine Drainage: Concept

Biological processes have been suggested as one future way to treat acid mine drainage. Anaerobic biological processes yield H_2S from sulfate ions in acid mine drainage, but there are aerobic processes that would generate sulfur which, at least in some parts of the world, e.g., Brazil, is an imported raw material.

Although processes have been conceptualized for sulfur recovery from sulfate solutions, so far no commercial-scale process has been identified, and this possibility is identified as a concept for possible future investigation and development. At this time, not enough is known to be able to even start to evaluate the possible economics of such a process. The possibility of employing rotating biological contactors, for example, for such a process may offer some opportunity to make it more practical.

GOLD FROM MINE-MILL EFFLUENTS

3. Giant Yellowknife Mines Ltd.

Giant Yellowknife Mines Ltd. is located close to the Arctic Circle on the shores of the Great Slave Lake in the Northwest Territories of Canada. It processes 1,215 short tons of ore per day by flotation to yield just over 100 short tons/day of concentrate which is roasted. The calcine is washed and cyanide leached. The tailings pond receives flotation tailings, cyanide-leached calcine tails, and a cyanide leached fluedust tail. Tailings pond liquids are decanted and treated by alkaline chlorination to destroy cyanide and precipitate base metals, then treated with ferric sulfate to remove arsenic as ferro arsenate which is precipitated and settled in a final settling pond before being decanted and discharged to a creek flowing into Great Slave Lake. This final decant solution flows by gravity through three carbon adsorption columns in series for gold recovery.

Effluent Gold Plant Capacity:	312 million gallons (1,415,000 m^3/d) were treated in 1983, with a gold content of over 3,000 oz., clearly a worthwhile target.
Operating Season:	5 months during summer only. The total volume of solution is treated over a short season; this has been taken into account in the plant design.
Number of Adsorption Stages:	3 stages.

Design of Columns:	Upflow Cortez-type columns with 2% open area in the plate distributors.
Feed Solution Tenor:	pH 7.5 with 0.0008-0.002 oz. Au/t.
Carbon Loading:	65 oz. gold per ton carbon on loaded carbon shipped for elution.

Gold Recovery from Carbon:

Formerly loaded carbon was shipped to a smelter which worked out at a cost of over C$5,000 per ton carbon in road freight ($344/t), the cost of the carbon smelted, smelter charges, and recovery losses.

Giant is evaluating the cost of installing their own carbon elution and regeneration plant at the site. Meanwhile, the most economically attractive approach is to ship the carbon for elution to a custom elution plant in the U.S.A.:

N. A. DEGERSTROM, INC.
N 3303 Sullivan Road
Spokane, WA 99216
(509) 928-2987
James A. Bradbury
Chief Metallurgical Engineer

After elution, the carbon is sent for thermal regeneraion in Oregon before being returned to Yellowknife.

Discussion:

Gold recovery at Giant Yellowknife could be inserted before or after the cyanide treatment plant. In this case, it was inserted after water treatment with no detrimental effect on gold recovery. This indicates that gold cyanide is not decomposed in the alkaline chlorination step.

Recovering gold by carbon adsorption after cyanide destruction has other advantages. Firstly, most of the base metals are removed so the carbon adsorbs less of them, and there should be less interference with gold adsorption.

Giant tailings are frozen for much of the year. Even in summer, only the upper layers of the pond thaw so the decanted solutions drained from the tailings remain cold. At low solution temperatures, the density is higher, and this should be taken into account when designing fluidized bed adsorption units.

Giant has experimented with several carbon adsorption systems and found that unless carbon is fluidized correctly, adsorption recovery is poor.

The economics of elution and regeneration of carbon on a small scale is poor considering capital and labor requirements. For a conventional elution and regeneration plant to treat one ton carbon per week, the cost was estimated at C$400,000.

4. Vaal Reefs Exploration and Mining Co. Ltd.

In the South African gold mining industry, there are a number of process streams in which gold values of less than 1g Au/t solution are recoverable using carbon columns. DAVIDSON and STRONG (1983) reported a new fixed-bed carbon adsorption system in which barren solutions of less than 0.01 g/t can be achieved using activated carbon.

RANDOL (1983) described the fixed-bed carbon column installed at Vaal Reefs Exploration and Mining Company Ltd.'s West Plant where a Phase I commercial-scale test plant using the Anglo American Research Laboratories design was installed.

This carbon column plant operates in a downflow mode, and it has demonstrated that under certain conditions, very high gold loadings (to 30 Kg Au/t) can be achieved from very low gold tenors (around 0.15g Au/t). Operating large diameter carbon columns in a fixed-bed mode is a major breakthrough.

Phase I Capacity. The plant is designed to treat 150,000 m^3/mo of solution (5,000 m^3/d) based on results achieved in 3"Φ test columns in a pilot plant. Up to July, 1982, when this plant was visited, it had treated 80,000 m^3/mo or 110 m^3/h of solution. The limiting factor proved to be the screen panels in the columns which buckled at design capacity and will, by now, have been redesigned.

Feed Solution:

Gold plant tailings filtercake is repulped after drum filtration in the gold plant. On reaching the uranium plant, the pulp is dewatered again, and the solutions are returned for incremental gold recovery through the carbon columns.

Feed Solution Grade:	Typically 0.14-0.15g Au/t.
Suspended Solids:	10-15 mg/l.

Use of Column Barrens:

After residual gold recovery, the solutions are used as washwater on the gold plant filters.

pH Control:

Solution pH is adjusted in a feed solution reservoir to pH 7.5. This reservoir is located ahead of the carbon columns and receive solution at pH 10. Concentrated H_2SO_4 is added at the tank inlet, the rate of addition being controlled by a valve activated by a pH meter in the tank.

A dangerous situation arose when the level of solution in the reservoir dropped to a level where the pH meter was no longer immersed in the solution. Acid addition continued until the pH solution dropped to 1.5. The barren solution after the carbon columns was used as gold plant filter wash solution and, at this pH, filter operators were rescued from the effects of cyanide toxicity. This situation will not recur again but is mentioned to alert others who may be tempted to reap the attractive benefits of low pH carbon adsorption.

Solution Tanks:

The solution reservoir tanks and pipes are rubber-lined mild steel.

Carbon Columns:

Three rubber-lined steel ion exchange columns are used. The columns are 2.13m Ø. Carbon fills the space between the screen floor and a screen at the top of the column. The steel columns are 3.7 m high are are designed so that carbon can be drained from the bottom.

VAAL REEFS WEST
(FIXED BED CARBON COLUMNS)

Internal Screens:

Internal screens in the carbon columns are flat circular wedgewire screens fabricated from stainless 316 steel with nominal 2,130 mm diameter. Five panels are supported on a 25.4 mm x 6.3 mm frame made of stainless 304 steel plus interbars.

HUB-TYPE WEDGEWIRE SCREEN INLET & OUTLET

The screen aperture is nominally 0.5 mm. The lower wedgewire screen is covered by a 3" layer of plus 3/16" gravel to compensate for non-uniformity of the wedgewire screen gaps. Because the screens are not uniform and because the carbon contains a fraction of smaller particles, it was not possible to backwash the columns as had been planned. A flat screen of such a large diameter, even with reinforcement as provided here, has proven not to be a good idea. Initially, the screen panels buckled.

The plant staff were under the impression that a lateral hub-type screen with spiral windings of stainless wedgewire would be mechanically preferable to screen panels.

Representativs of Johnson Screens U.S.A. in South Africa were working on the fabrication of suitable hub-type screens:

S.A. SCREEN AND INDUSTRIAL SUPPLY
Post Office Box 82040
Southdale 2135
South Africa
(011) 68-5494/5

It is believed that CALGON CORP. supplies a carbon column for water treatment which probably would work well for this application as well.

Carbon Used:	Le Carbonne G210, 0.68 mm x 1.2 mm.
Carbon Capacity:	Each column holds 4.4 t carbon.
Pumps:	Pumps feeding the columns are designed to exert a maximum pressure of 220 k Pa.

Pressure Drop:

The pressure drop across the three columns when operated at 80,000 m^3/mo (110 m^3/h) was measured at 100 k Pa. The pressure drop across the three beds in variable. It drops immediately after each acid treatment of the carbon.

Acid Treatment:

In order to enhance the metallurgical performance of the columns and to prevent calcium carbonate fouling, provision is made to isolate any column as required and to fill it with acid and then for draining of the acid after the appropriate soaking period. At the time of the visit, the columns were being acid washed every two days using 4% HCl.

Several acid wash techniques were experimented with. For some time, the columns were washed with acid every two days using cold 4% HCl. Acid was injected through the bottom to fill the column with acid. If there were not problems in disposing of the acid, it would be desirable to inject a slug of acid daily.

At the time of the visit, acid washing had been reduced to once every week. The three carbon columns were simply filled with 12% HCl and allowed to stand for 24 hours before draining the columns to reclaim the acid before putting the columns back on line. The acid becomes deep blue in color indicating that base metals are stripped from the carbon in the process. No gold was detected in the acid effluent.

In pilot testwork, a slug of acid was simply pumped through the columns daily, and this had resulted in phenomenon gold loadings.

EFFECT OF ACID WASHING

It has been found that after acid washing, three changes occur:

- Enhanced gold loading on the carbon is possible.
- Incipient breakthrough of gold in the tailings solution is avoided.
- The pressure drop across the columns is reduced, and flowrate capacity is increased.

A negative aspect of acid washing is that it causes corrosion of the stainless steel screens.

Barrens:

Under optimum conditions, a barrens of 0.004g Au/t is achieved which was not typical of this plant, however. During the visit, tails ran 0.02g Au/t and, after a 3-day acid wash experiment, fell back to 0.011g Au/m^3. On the following day, gold levels in the barrens were back to 0.018 g/m^3. The test program showed clearly that more frequent acid washing with dilute acid has a more beneficial effect than less frequent, more concentrated acid washing.

Gold Loading:

In pilot plant tests, carbon loadings of 1.5 Kg Au/t can routinely be achieved from solutions with 0.15g Au/t. Acid washing every 5-6 days with one bed volume 5-6% HCl resulted in loadings of 2.5 Kg/t carbon at the time the third column broke through, achieving recoveries of 98% or more.

Later pilot plant tests with acid washing of the carbon on a daily basis achieved loadings to 30 Kg Au/t and 70 Kg Cu/t carbon.

At the time of the visit, carbon loadings up to 5.5 Kg Au/t carbon were achieved from the lead column before breakthrough occurred on the third column, also from 0.15g Au/t solutions.

Column Profile, July 4, 1982:

	Inlet	Solution Tail	C Loading Calculated
Lead Column	0.15g Au/t	0.10g Au/t	5.19 Kg Au/t
B Column		0.06g Au/t	2.24 Kg Au/t
C Column		0.020g Au/t	1.35 Kg Au/t

Elution:

The requirement for elution of 4.4t carbon would arise every 3-4 months. Carbon is simply drained from the lead column when this is needed.

Sampling:

A daily composite sample of feed and tail solution from each column is collected. These were assayed for gold.

It was anticipated that Phase II of the program would be implemented in which the full 250,000 m^3/month of solution available from the repulped gold plant could be treated for gold recovery using similar equipment.

More information could be requested on the design, operation, and performance of this type of carbon column from:

5. Welkom Division, Western Holdings Ltd.

At Welkom, a NIMCIX column using activated coconut charcoal rather than resin beads has been successfully installed to recover gold from up to 300,000 m^3/month dilute tailings decant solution as described in the following trip report extracted from RANDOL (1983).

The multi-stage carbon column employed here was installed by:

DAVY McKEE SA (PTY) LTD.
Post Office Box 8608
Johannesburg 2000
(011) 28-5920

The basic principles of the NIMCIX design is depicted in the following diagram. Feed solution flows up the column which has nine stages located one on top of the other and separated by perforated plate distributors. The bottom plate distributor is believed to have been modified to incorporate "bubble caps" which are a patented design feature of the NIMCIX column owned by MINTEK. Information on NIMCIX columns can be requested from:

DATE OF VISIT

11 June 1982

INTRODUCTION

Phase I of this report described the fluid bed carbon columns which were then being installed to recover gold from tailings reclaim water at the WELKOM millsite. This was described in Appendix 1 page 509-511.

This report update provides some actual operating information and relates some of the problems to be expected with this type of column during the startup phase. Not all this information came from ANGLO AMERICAN CORPORATION and some of it may not be accurate.

The column recovers gold from a low tenor solution at a low pH which results in enhanced gold loadings but also enhanced copper loadings. Teh high copper loadings seem to result in a more difficult elution of gold and ultimately in a high copper bearing cathode and dore bar.

PLANT STARTUP

Startup had been scheduled for September 1981, but actual commissioning took place in January 1982. The adsorption has functioned satisfactorily but there were initial problems with the elution and electrowinning steps.

TOTAL CAPITAL COST

R1.6 mm (about US $1.4 million).

COMMENTS ON COMMISSIONING:

ADSORPTION CAPACITY

It was found that the column which had been designed for 260,000 m^3/mo (356 m^3/h) of solution throughput could easily handle this volume - up to 300,000 m^3/mo had been tested successfully.

BED EXPANSION Carbon bed expansion of 100-120% is experienced at a flowrate of 120 l/s through the 3.0 m Ø column which works out to about 1 m/minute flow velocity. Initially some problems were experienced with elutriation of carbon platelets from the column, some of which were of the correct carbon granule size as specified based on pilot tests.

CARBON DENSITY

Density of dry carbon is 450 Kg/m^3. The column holds a total of 15 t carbon with 1.5 t in each stage except the top one, which holds 3 t carbon.

CARBON USED LE CARBONE G210AS , 0.6 - 1.7 mm particle size (mean 1.2mm).

Several carbons have been laboratory tested but only one, G210 AS , met the bed expansion test criteria.

FINE CARBON RECOVERY

A fine carbon recovery system consisting of a stainless steel screen and a pressure filter is installed to recover any fine carbon particles from the conditioning column and carbon prescreening sections plus any spillage containing fine carbon prior to the water leaving the plant. Fine carbon must not be allowed to recirculate back to the main gold plant.

CARBON CONDITIONING

Carbon as received is conditioned by placing it in an 80 cm column for eight hours in which the flow in the full scale columns is simulated. This gets rid of the platelets that are most likely to be elutriated before they get added to the system and to some extent also conditions the carbon particles. Overflow from the conditioning column is pumped via the fine carbon recovery system to prevent it from entering the gold plant process water.

NUMBER OF STAGES

The continuous adsorption column was designed to have ten stages. In fact, it was constructed with a double top stage, which means it has nine stages of which the top one has twice the capacity.

STAGE SEPARATORS

Perforated plates between each stage have holes sized for an upflow velocity of 120 l/sec. The holes in the separators have a 16 mm Ø.

pH CONTROL 5-10% H_2SO_4 is added as needed to the feed solution to adjust the pH of the feed to pH 7-7.5. On the date of the visit, the solution pH was 6.8. Sulfuric acid is mixed into the solution by an on-line static mixer. Since the pH of feed solution as received is 7.5 to start with, very little acid is added for pH adjustment.

ADSORPTION ENHANCEMENT

Based on findings of AARL, which have also been proven at the VAAL REEFS test columns, periodic flushing of the column with a slug of acid enhances gold loading capacity of the columns. WELKOM tested the use of 1 m^3 slugs of hydrochloric acid on a weekly basis using a three minute contact with 3% v/v HCl solution. However, this did not result in any noticable degree of improvement in adsorption and has been discontinued for the time being.

COLUMN CORROSION

The column is constructed of mild steel. Periodic checks are planned to monitor corrosion.

FEED SOLUTION TENOR

Feed solution to the columns were designed for 0.044 g Au/t solution based on typical values tested in the past.

After the plant was installed, grade of feed solution dropped to 0.026 g Au/t possibly because the operations feeding the recovery system had become more careful.

Cyanide concentration in the feed solutions is minimal at around 0.001% NaCN.

FEED IMPURITIES

Copper concentration in the feed solution is 2.5 ppm. The pH of the solutions as received, is around 7.5, so the H_2SO_4 dosing system need not be used most of the time.

SUSPENDED SOLIDS

Feed solutions with up to 2000 ppm solids, have at times been treated, which causes some problems.

CARBON FOULING

Silica adsorbs on the carbon to a degree, but did not seem to be adsorbing beyond a certain plateau level. SiO_2 is believed to be removed during elution in the caustic solution.

Calcium loads up to 4000 ppm on the carbon, but does not appear to interfere with gold adsorption.

GOLD ADSORPTION

Gold loading on carbon from 0.026 ppm Au solution were only around 250 g Au/t carbon. From 0.032 g Au/t solution feed loadings of 549 g Au/t were typical. Although acid treatment of carbon did not produce the expected results, close attention to the regeneration process has greatly improved recovery. Loadings of the order of 400 g Au/t C are now typical.

ADSORPTION PROFILE

A carbon adsorption profile for the adsorption column is shown in the following data - clearly taken on a day when gold solution tenor was closer to 0.03 g Au/t.

Copper loading in this set of data is reasonable at 7000 ppm. It has been reported that copper can load up to 22,000 ppm on the carbon on occasion.

MINTEK suggested adding cyanide to the feed solution to convert Cu^+ to $[Cu(CN)_5]^{-4}$ in order to reduce copper loading onto carbon. $[Cu(CN)_5]^{-4}$ loads very slowly onto carbon compared with CuCN and $[Cu(CN)_2]^-$, however this equilibrium between copper cyanide complexes is also cyanide dependent.

CARBON LOADING PROFILE

Stage	Au g/t	Cu g/t	Zn g/t	Ni g/t	Fe %	Ca g/t	SiO_2 %
1	436	7000	2700	2500	2.13	4200	1.26
2	342		2500	2400	0.92	3800	1.33
3	302		2700	2300	0.81	4200	0.71
4	325		2700	2500	1.02	3600	0.80
5	330		2700	2100	0.70	3600	0.56
6	324		2500	2500	0.70	2900	0.45
7	324		2500	2400	0.80	2800	0.47
8	248	5900	2500	2000	0.73	3000	0.51
9	225	6300	300	2100	0.99	3500	0.74

It is claimed by some, that carbon adsorption of copper is enhanced at the lower operating pH used here.

CARBON TRANSFER

The NIMCIX-type upflow column employed for carbon adsorption was basically designed for use with resin ion exchange beads which of course are more spherical than the carbon which has a platelet shape.

The sequence for carbon transfer in the NIMCIX-type column is described in the Appendix I trip report and basically includes a settling period followed by a brief backflush period during which a controlled amount of carbon is supposed to transfer down the column from each stage to the next. In this case, however, during the 45 minute period while the inventory from the bottom stage is transferred for elution, the complete carbon contents of the column settled to fill the first three stages leaving the rest empty.

When the column went back on forward flow, the carbon fluidised up the column again, but in the process, a considerable degree of backmixing resulted which probably reflects the design of the plate separators. One alternative was to fit bubble caps on each stage separator which would have been expensive.

The column has now been provided with provision to maintain upflow during carbon transfer. This is expected to prevent settling of carbon in the lower stages. Initial results look promising and it is hoped that interstage mixing problems will have been overcome by the time this report is printed.

CARBON RESIDENCE TIME

Carbon is transfered at the rate of 1.5 tons, twice a week. The operation does not wait for gold to break through before transfering a batch of carbon for elution.

RECOVERY

Tails from the carbon column are very low and about 70 - 80% of the gold in the feed is recovered at present. It is hoped that 90% recovery will be achieved when interstage mixing problems have been solved.

0.1 ppm Au solutions, yield tails at around 0.01 ppm Au and a carbon loading of 1 Kg Au/t carbon under standard adsorption practice at pH 7.5.

GOLD PROUCTION

5 Kg Au per month.

ELUTION

A ZADRA-type elution is employed and 90-95% of the adsorbed gold is eluted each cycle into 8-10 m^3 eluate from 1.5 t carbon.

After each cycle, about 25% of the spent electrolyte from the previous elution and electrowinning cycle is discarded and replaced by fresh eluant solution.

Elution follows the following steps:-

1. Transfer loaded carbon to elution column.
2. Drain the carbon, 6-8 hours.
3. Displace the transfer water with 2 bed volumes of process water to flush out any solids.
4. Pass hot NaCN/NaOH eluant through the column upflow. Collect the eluate in a tank. Recycle for 48 hours via a steady head tank.
5. Electrowin gold from the eluate.

In order to overcome problems with precipitation of solids in the heat exchanger it is necessary to wash the carbon with softened water to remove any entrained process water. It is worth recording that it is now usual to wash eluted carbon prior to regeneration as well as prior to elution. This reduces the level of entrained eluate with dissolved salts.

ELUTION CONDITIONS

1% NaOH, 0.1% NaCN at 95-98°C. At WELKOM, water boils at 95°C.

WELKOM were experimenting with a modified eluant of 0.3% NaCN and 2.5% NaOH.

Carbon batches of 1.5 t each, are eluted twice per week. Each elution cycle takes three days.

Elution rate is temperature dependent. One plan was to try to achieve 101-102°C by increasing the salt content of the eluate.

It is found that NH_3 is generated during elution as well as during electrowinning.

ELUTED CARBON

Carbon gold loadings after elution are around 30 g Au/t, which indicates an effective elution. However, the loaded carbon transferred to elution is loaded to only 300-400 g Au/t.

ELECTROWINNING

Initially, the NIM I cell (carbon granule electrodes) would not plate more than 5% of the gold per pass.

At a copper: gold ratio in the eluate of 40-50:1 copper plated onto the cathodes.

The NIM I cell that was designed to recover 3 Kg Au per cycle, ended up plating up to 40 Kg copper each cycle. There was also a rapid anode corrosion in the NIM I cell even when 2% NaOH was used in the eluate.

Many approaches were tried to overcome the problem, including the multiple reuse of the eluant, but copper still continued to build-up.

The operation produced copper bars with some gold content, which were sold to the RAND REFINERY.

The NIM I cell uses granular carbon chips as a cathode and produced gold and copper plated carbon chips. These did not smelt readily nor could gold be backplated onto titanium sheets with much success.

The results have greatly improved since the new version of the rectangular MINTEK cell has been employed.

MINTEK CELL

0.7 x 0.7 m cross section cathodes, of which there are six with seven stainless steel mesh anodes in a rectangular stainless steel bath. The cell tank is connected to the cathodes and serves as the busbar for the cathodes.

The cell is designed to treat 5000 l/h of solution.

In the new MINTEK cell, some corrosion of the stainless steel anodes was still being observed even at relatively high concentrations of OH^-.

Two sources indicated that only 3-6% Au was plating onto the steel wool cathodes. It was indicated that copper was still plating on the cathodes as would be expected. One industry source has suggested that by increasing the cyanide concentration in the eluate, copper plating would be inhibited.

WELKOM indicate, however, that cyanide is effectively destroyed in both the hot elution process and in the electrowinning cell.

According to two sources, only 3-6% Au was plating onto the steel wool cathodes. Copper was still plating on the cathodes as would be expected.

One industry source has suggested that by increasing the cyanide concentration in the eluate, copper plating would be inhibited. However, WELKOM indicate that cyanide is effectively destroyed in both the hot elution process and in the electrowinning cell.

There may be no cost effective solution to the problem other than to find a market for the gold that does not penalise heavily for the copper in the dore. Several factors could influence the copper content in the dore bar:-

1) Keep a high cyanide concentration in the feed solution to the column. At low operating pH, however, this is not likely to be possible.

   Carbon in the presence of copper in this low pH range catalytically destroys cyanide.

   High copper loadings seem to be part of the mechanism whereby high gold loadings are achieved.

2) Electrowin at below 2.5 volts. In Australia using cylindrical steel wool cells, gold has been selectively plated from eluates containing 2000 ppm and more Cu. It is noted that WELKOM's data sheet shows operation of their cell at 2.5-3.0 V but this requires confirmation as previous data showed a higher operating voltage.

3) It is not known whether it is relevant or not, but the Australian operation which plate gold selectively in the presence of high copper also use hot eluates which have not been cooled by a heat exchanger to preheat incoming eluant.

6. Homestake Mining Company, Lead, South Dakota

Homestake Mining Company is known to recover gold from reclaimed mill tailings decant solution. Although carbon columns are used for this purpose, no further details were obtained.

Appendix I also includes a description of the biological effluent treatment facility at Homestake's Lead operations. This facility uses rotating biological contactors with nutrient enhancement of the feedwater to oxidize cyanide and remove metals in the first stage followed by ammonia removal in the second. It is believed that low-level residual gold values in the effluent are also recovered with other metals in the biomass sludge generated by the RBC process. To date, no definitive data on this potentially useful aspect have been released by Homestake Mining Company.

Chief Environmental Engineer

7. Pinson Mining Company, Winnemucca, Nevada

Pinson Mining Company has installed fluid-bed multi-stage carbon columns to recovery incremental gold values from tailings return water reclaimed from their tailings dam for use in their milling circuit. No details were obtained on the performance of this recovery system, but these could be obtained from:

PINSON MINING COMPANY
Post Office Box 192
Winnemucca, NV 89445
(702) 623-5036
R. Bruce Thorndycraft
Mill Superintendent

The system installed at Pinson Mining is similar in principle to that installed at Giant Yellowknife in that the upflow fluid-bed carbon adsorption stages are located side-by-side and connected by gravity flow. At Pinson Mining, the loaded carbon is eluted and regenerated with carbon in their main CIP plant. The fact that no huge lead-times or freight bills are incurred means that Pinson Mining has less motivation to load gold to the maximum possible loadings on their carbon before it is eluted. In their case, inventory lockup would be a bigger factor.

8. Buffelsfontein Gold Mining Company, Stilfontein, South Africa

Buffelsfontein Gold Mining Company in South Africa also recovers low-grade gold values from gold mill tailings filtercake solution after it is repulped before being treated in their uranium leach circuit. In this case, the tailings are repulped in acidic water, and fine activated carbon is added to the pulp in the process. Final tails are floated to recover pyrite values, and residual gold values that were in the repulped tailings end up being recovered with the pyrite concentrate which contains the fine activated carbon. During roasting of this concentrate, the carbon is ashed, and gold is recovered in a subsequent step in which the calcine is leached in cyanide.

Details of this process were not released by Gencor Ltd., the mining house which manages Buffelsfontein operations. However, VAN ASWEGEN (1985) will describe the process and its performance later this year in Cannes.

The interesting aspect of this approach is that incremental gold that could otherwise be recovered by carbon columns such as at Welkom or at Vaal Reefs West, mentioned above, now is recovered out with the need for a special treatment plant. The only equipment needed is a device for addition of the fine carbon to the pulp. Because the carbon added is finely divided, adsorption kinetics are faster than for regular granular coconut carbon. However, it remains to learn what kind of recovery efficiency of the soluble gold in the pulp is achieved and what the flotation recovery of this carbon is, as well as what recovery is achieved in the concentrate roasting and leaching step.

The person at Gencor who has been deeply involved in the development of this process application at "Buffels" can be reached as follows:

URANIUM

9. Wyoming Minerals Corp., Bingham Canyon, Utah

The following trip report was excerpted from RANDOL (1980) and, undoubtably, many details regarding the contact, etc. may have changed. This operation employs a Higgins Loop ion exchange contactor illustrated below:

WYOMING MINERALS CORPORATION
BINGHAM CANYON

ADDRESS	Wyoming Minerals Corporation P.O. Box 311 Bingham Canyon, UT 84006
CONTACTS	Ron Platzke, Plant Manager Virginia Owens, Plant Chemist Ray Aitken, Purchasing Agent
TELEPHONE	(801) 364-1071
CORPORATE	Wyoming Minerals Corporation 3900 S. Wadsworth Lakewood, CO 80235
CONTACTS	J. C. Compton, Executive Vice President Fred Hohne, Vice President Carmine Mancuso Dr. Eric Tiepel Frank Ludeman
TELEPHONE	(303) 988-8530
RESEARCH	Westinghouse Research & Development Center Pittsburgh, PA
CONTACT	Mike Skriva
TELEPHONE	(412) 256-5035
CAPACITY	Three CHEM-SEPS units treat 6,600 US gpm solution (1500 m^3/h) i.e. 2,200 US gpm each or 500 m^3/h. This is average flow rate. Loading section ϕ is 8 ft. Since the units pulse 45 seconds every six minutes, the flow rate during the 'Run' mode must be 8/7 x 2,200 US gpm = 2500 US gpm (545m^3/h). This is considerably less than was originally designed based on pilot plant work.
SPECIFIC FLOW RATE	Originally the units were designed for 55 US gpm/ft^2 2200 US gpm average flow rate corresponds to 44 US gpm/ft^2 specific flow rate. 2500 US gpm flow rate during 'RUN' mode corresponds to 50 US gpm/ft^2.
NOTE	Wyoming Minerals Corp is sensitive about information on the HIGGINS LOOP operation. The information provided here should be regarded as confidential even when talking to Wyoming Minerals' staff.

Fig. 1—Diagram of the ion exchange operation.

URANIUM GRADE	6-7 ppm U_3O_8 Grade may fluctuate to 5 ppm depending on the weather due to run-off dilution or depending on which tailings piles Kennecott Copper leaches that day. This corresponds with 6,600 US gpm flow rate for 365 days/year at 6.5 ppm head grade and 1.5 ppm barrens, i.e. 0.005 g/l extracted.
URANIUM PRODUCTION	140,000 lbs. U_3O_8/year
BARRENS	Used to be 1.7 ppm U_3O_8, now barrens of 0.9-1.2 ppm are experienced. The 1.7 ppm U_3O_8 average includes the third HIGGINS LOOP unit which doesn't run as well and gives higher barrens.
UNIT SIZE	8 ft.ϕ at loading section, the units are 55 ft. high. The three HIGGINS LOOPS fit into a remarkably small building.
LOADING STAGE	Originally the loading stages were 8 ft. high. Now loading stages have been reduced to 5 ft. height to reduce the pressure drop across the resin bed which was causing damage to the resin beads.
RESIN INVENTORY	750 ft.^{3} resin per unit (21.2m^3 each) Originally resin inventory was 1000 ft.^{3} (28.3m^3) prior to modification of the units.
RESIN TYPE	Macroreticular resin. Porous beads. DOWEX MSA 1 16-30 mesh (U.S. Std. Sieve)
RESIN COST	About \$125/ft.^{3} resin delivered \$4400/m^3 R 3500/m^3
RESIN SELECTION	DOWEX MSA1 was selected because it is both mechanically strong and resistant to osmotic shock. Ron Platzke claims losses are now such that the operation is economically viable. Gel type resins resulted in impossible resin losses to the extent that stable operation could not be achieved. DOWEX MSA1 has been used for the last 1½ years and has given a stable operation.
RESIN LOADING	1 to 2 g/l

RESIN LOSS

Resin loss in the CHEM-SEPS unit is high and is caused by:

-Osmotic Shock
-Mechanical Movement of the Resin
-Valves Closing on Resin
-High Pressure Drop Across the Resin Bed

Ron Platzke claims that resin loss is a result of valves closing on beads is low.

In the two years of their program with HIGGINS LOOPS to date Wyoming Minerals Corp. have used up about 12,000 ft.^{3} (340M^3) of resin in the three HIGGINS LOOPS WITH 750 ft.^{3} (21.2m^3) resin inventory each. This is roughly 270% per annum of resin inventory lost per year. A disastrous situation.

When Wyoming Minerals Corporation installed their first unit, the 1000 ft.^{3} resin inventory was destroyed within 6 hours. The unit had been started up under Chem-Seps supervision.

The resin inventory was replaced and it too broke in a day or so.

Then after performing some osmotic shock tests, the unit was filled with DOWEX MSA1 resin. This resin load lasted a week.

Each 1000 ft.^{3} resin load was worth $100,000, so in less than two weeks of running the unit, $300,000 worth of resin was destroyed. As a result, Wyoming Mineral's Corporation undertook a major resin test program, and modified the HIGGINS LOOP to downgrade its capacity thereby reducing the affects on resin loss.

Wyoming Minerals found that the resin breakage due to high osmotic shock and high mechanical shock applied t resin simultaneously was greater than the sum of the resin loss due to the two influences separately. In fact it was greater than the product of the resin losses from the two causes because the resin simply 'explodes'.

Mike Skriba of Westinghouse Research & Development has developed an RST (resin strength test) procedure and apparatus to measure resin losses on samples.

Resin losses now are believed to be around 100% PA of inventory or 54 PPM of flow rate of feed which is not bad at all.

Wyoming Minerals Corp. is actively searching for better resins and have developed a set of specifications which will enable resin to be manufactured for the HIGGINS LOOP that will last much better.

When comparing resin loss data for different CIX systems it is very misleading to compare on the basis of percent of resin inventory lost per year.

The HIGGINS LOOP treating 2200 US gpm has a resin inventory of only 750 ft.^{3} (21.2m^3).

NIMCIX at 1200 gpm requires a resin inventory of 5300 ft.^{3}. (150m^3).

Hence a 100% per year loss of resin inventory on a Chem-Seps unit at 2200 US gpm flow is equivalent to 5.3 PPM of flow.

5.3 PPM resin loss on a NIMCIX unit at 1200 gpm flow with 5300 ft.^{3} resin (150m^3) inventory would work out to 12.6m^3/year resin loss or 8.4% of the resin inventory.

It is therefore more appropriate to compare resin losses in terms of ppm of solution treated or volume of resin lost per unit of uranium produced.

Cost of resin loss per m^3 feed treated and per pound of U_3O_8 produced is compared below for 30%, 50% and 100% per year resin inventory losses on a Chem-Seps unit.

COST OF RESIN LOSS

21.2m^3 (750 ft.^{3}) Resin Inventory @ \$100/ft.^{3} per unit. Each unit produces 4.38mm m^3 x 5ppm x 2204.6 tbs = 48,280 lbs U_3O_8

At 30% Resin Loss Per Year

4.38 million m^3 solution treated per year per unit
= 6.36m^3 (225 ft.^{3}/yr) resin loss per year
= \$28,000 per year
= \$0.58 per lb U_3O_8 produced

At 50% Resin Loss Per Year

4.38 million m^3 solution treated per year per unit
10.6m^3 (375 ft.^{3}) resin loss per year per unit
= \$46,900 per year (\$125/ft^3)
= 0.97 per lb U_3O_8 produced

At 100% Resin Loss Per Year

4.38 million m^3 solution treated per year per unit
21.2m^3 (750 ft.^{3}) resin loss per year per unit

$94,000 per year cost of resin per unit ($125/ft^3)
$1.95 per lb U_3O_8 produced

RESIN DENSITY — The DOWEX MSA1 resin has an SG of 1.08 compared with SG = 1.1-1.2 for gel types. Resin density is not as important a feature for this type of contactor as for upflow systems.

FEED SOLUTION — Product of heap leached tailings dump rich in copper and high in particulates.
pH = 2.8 - 3.0 as received.

No resin poisons.

Very low SiO_2 content in feed.

ELUTION — Elute with three bed volumes of 150 g/l (3N)H_2SO_4
No copper gets carried over in the eluate.

ELUATE — 300-500 PPM U_3O_8

TEMPERATURE — 80°F or higher.

RUN/PULSE CYCLE — Resin is moved every 6 minutes. Each pulse lasts 10 to 15 seconds but the whole sequence including opening and closing valves takes 45 seconds.

SILICA — Very low SiO_2 buildup experienced--Less than 1% per year SiO_2 on the resin. pH is kept high enough to reduce the SiO_2 problem. At low pH's Ron Platzke believes that SiO_2 polymerises and "glues up."

RESIN REGENERATION — Not required at Bingham Canyon.

PARTICULATES — Suspended solids content of the feed solution at Bingham Canyon are high and vary considerably. Suspended solids of 1000 ppm are not uncommon. Variation depends on rainfall or snow melt runoff.

The particulates consist of flakelike particles of organics from the tincans used for precipitating copper cement.

In addition there are varying amounts of silt in the feed.

Particulates have a big impact on the HIGGNS LOOP operation. As particulates in the feed increase the pressure drop across the resin bed in the loading stages increases significantly.

Particulates also cause severe abrasion of pump.

PARTICULATE REMOVAL

Particulates are controlled as much as possible through three factors:

1. Installation of a one stage wooden settling tank ahead of the CIX unit.
2. Overflow solution is then filtered through sixty four ZURN strainers.
3. One section of the HIGGINS LOOP is used to backwash solids accummulated during the loading phase. The packed resin bed acts as a very good filter and will accumulate any solids present in the feed.

The HIGGINS LOOP is operated on a very short cycle of 6 minutes. The shorter the cycle, the less solids have a chance to build up in the loading stage between backwashes.

MAIN LOOP VALVES

21SSB Crane Monarch valves with squeegy disc wiper to reduce resin damage.

MAIN COST FACTORS

- Operators & Maintenance
- Resin Loss
- H_2SO_4 for Elution
- Na_2CO_3
- SX Chemicals
- Utilities e.g. Pumping Costs

MANPOWER REQUIRED

A total of 16 people plus three maintenance engineers are required to operate the plant.

5 foremen
6 process technicians
1 metallurgist
2 laboratory chemists
1 manager
1 clerk
16 Total

3 Maintenance Engineers

After Jacobs Constructors, who built the plant, left the site one of their crew left to go into business for himself and set up a small company that maintains the CIX units under contract.

OPERATIONAL AVAILABILITY

Now improved to 97-98%. Expected to drop to 90-98% as the new units get older and require more maintenance.

OPERATING SENSITIVITIES

All concerned emphasized that the HIGGINS LOOP is a very sensitive unit to operate.

When resin is pulse transported around the column in plug flow fashion it moves in what has been described as a "stick-slip" method. This leads to tremendous water hammer possibilities and enormous pressures seem to build up in the loop. Strain guage tests showed incredible forces in the column that could nly be explained by resin bridging effects.

At times when resin blinds the collector screens drawing barrens from the loading stage of the loop, tremendous forces build up which bend the collectors which are very robustly constructed. Forces up to 1000 PSI on the collectors are experienced at times.

WMC SATISFACTION WITH HIGGINS LOOP

Mike Skriba at Westinghouse Research & Development Center, Pittsburgh indicated that the HIGGINS LOOP could be developed into the best system for continuous ion exchange in the world for cases where:

(1) Feed rate is very high
(2) Recoverable grade is very low
(3) Value of recovered material is high
(4) Sophisticated operators with prior experience running a HIGGINS LOOP are available.
(5) There is a space constraint for the plant.

RESIN REGENERATION

If resin regeneration is required then a means would have to be built into the system to do so.

The resin regeneration cycle would be different to other CIX systems.

The whole hoop might be taken off line temporarily and the whole resin inventory regenerated simultaneously.

MODIFICATIONS

Numerous modifications were made to the units at Bingham Canyon.

1. The LOAD section has been reduced in size from 8' to 5' to reduce pressure drop across the resin bed.

2. The ferric strip stage was removed. Ferric is now stripped from the resin in a different manner.

3. Flow rates to the units were cut back to 2200 US gpm average.

4. Several piping modifications have been made by Wyoming Minerals Corp on the units.

5. Wyoming Minerals Corp have modified the solution tenor control system.

10. Cotter Corporation, Schwarzwalder Mine, Golden, Colorado

Cotter Corporation discharges minewater to a creek that ultimately gets into the Denver drinking water supply. The Colorado Dept. of Health has insisted on the most demanding effluent water quality limits for both uranium and base metals as shown below (from PALMER, et al., 1984). The water treatment plant is described in Appendix I.

Uranium is recovered from this minewater stream containing only 3-5 mg/l using a new design of a continuous downflow ion exchange adsorption unit resulting in extraordinarily low levels in the effluent of uranium (10 ppb) and base metals. In addition, eluate generated are concentrated enough (12g U_3O_8/l to be used as pregnant solution at Cotter Corporation's mill in Canon City.

This incremental resource recovery plant performance is quite remarkable and is a great credit to its designer:

HIMSLEY ENGINEERING
250 Merton Street
Toronto, Ontario M4S 1B1
(416) 485-4441
Alec Himsley

Element	Feed (mg/l)	IX Effluent (mg/l	Discharge Limit mg/l)
Uranium	3-3.5	LT 0.010	0.06
Cadmium	0.002	0.0004	0.0004
Copper	0.02	0.005	0.005
Lead		0.005	0.032
Zinc	0.0026	0.05	0.05
Radium (p Ci/l)	50-100	5	5 Total
Arsenic		0.05	0.05

11. Quivira Mining Company, Ambrosia Lake, New Mexico

At Ambrosia Lake, New Mexico, the Quivira Mining Company discharges large volumes of minewater from a series of underground uranium mines. Water seeps from the tailings dam (which is acidic) and, together with discharged minewater, finds its way into underground workings via drillholes and fractures. Underground, it leaches uranium from the stopes which, to comply with the NPDES discharge permit, must be removed before the minewater can be discharged.

This operation is described in an Appendix I trip report. It is, however, an example of how simple, one or two-stage upflow fluid-bed ion exchange adsorption units are less

effective in treating solutions containing high concentrations of ions that compete for sites on the ion exchange resins.

In this case, to achieve an efficient uranium recovery from minewater with the composition that is encountered at the Ambrosia Lake operations, a multi-stage system such as NIMCIX or a downflow CIX adsorption unit, such as designed by HIMSLEY, would be likely to give a greatly improved performance.

More information is included in the trip report and also may be available from:

Jonathan Ma
Metallurgical Manager

It is important to note that when the KERMAC CIX system consisting of one or two CIX stages for uranium adsorption were installed originally, the quality of the minewater was markedly different with much lower TDS and sulfate level, and the system performed more than adequately. Formerly, the resin needed to be eluted only 16 times a month to keep uranium levels in minewater below 1 ppm U_3O_8 for discharge. Now, due to the changed water quality underground, 40 elutions per month are required, and eluate tenor has also dropped due to the lower loading on the resin when sent for elution.

12. UNC-Homestake Partners, Grants, New Mexico

United Nuclear-Homestake Partners operates a uranium mine and mill complex at Grants, New Mexico. Ion exchange is used to recover incremental uranium values from underground minewater and from tailings dam recycle water. Uranium levels in 1980 were 16-23 ppm U_3O_8 in minewater and 20-30 ppm in reclaimed tailings water.

Significant quantities of uranium were recovered from both types of solution using in-house ion exchange systems. As solution chemistry changed with time, it became increasingly difficult for their simple ion exchange system to reduce uranium values to below 1 ppm as required by the NPDES discharge permit.

It is known that around 1981, UNC-Homestake Partners installed a NIMCIX ion exchange plant to improve their uranium recovery performance for mine and tailings return water. No published data on the performance of this plant was located. However, more information would be available from:

September 4, 1984

Hans Von Michaelis
21578 Mountefield Drive
Golden, Colorado 80401

Dear Hans,

Further to our telecon I enclose some data on the El Teniente mine water solvent extraction project.

	Aqueous Flow Rate	Copper Production
Minimum	250 m^3/h	<1000 tons/year
Nominal	612 m^3/h	4060
Maximum	900 m^3/h	4611

At nominal flow rates and below the plant operates in a conventional counter current two extraction two strip mode. For higher flowrates the plant can operate with the agueous feed in parallel through extraction.

The flow is seasonal and in place with the spring snow melt. High copper tenors >2 gpl often coincide with high flows at the beginning of the run off.

I hope you find this brief description of use in your survey.

Sincerely yours,

DMC Engineers and Constructors

LEAD-ZINC

15. Cominco Ltd., Trail, British Columbia

At Cominco's Trail, B.C., plant, an award-winning water treatment plant was installed to treat thirteen effluent streams from their zinc operations and some from the lead smelter. This plant treats 6,500 m^3/d of effluent, including flows from various sewer systems from 20 separate areas at the Trail metallurgical complex, as described by WATSON and TURNBULL (1983).

At Trail, effluents are treated by the high density sludge process to yield a precipitate sludge containing zinc and lead which is returned to the lead smelter for zinc and lead recovery.

The plant recovers 98.9% of the zinc, 99.5% of the lead, 97.5% of the cadmium, and 92.9% of the suspended solids in the feedwater. Although there is no return on the capital invested (C$9 million), the recovered metal values have been found to offset much of the C$720,000 annual operating costs according to WATSON and TURNBULL (1983) which, in itself, is a remarkable achievement. ZINC

16. Noranda, Mattabi Division, Ignace, Ontario

Mattabi Division of Noranda Mines Ltd. operates a mine-mill complex recovering copper, lead, zinc, and silver from massive sulfide orebodies north of Lake Superior in Ontario.

Decanted solution from their large tailings dam, which is rich in sulfides, is collected and treated at a rate of 600 lgpm by lime precipitation. The water is treated by lime addition and aeration, followed by flocculant addition and settling in a plate pack thickener yielding a sludge containing 5-10% solids. The sludge contains zinc values and was returned to the zinc concentrate thickener where it was believed to be squeezed by the

weight of the concentrate and further dewatered before being shipped with the zinc concentrate, to a zinc refinery.

Certainly the revenues generated after freight by zinc values in the sludge that had been added to the concentrate would be minimal, and it has been learned that Mattabi no longer adds the sludge to their concentrate, but rather they are said now to add them back into the mill tailings.

In considering the value of zinc in precipitate sludges which may have to be shipped over many hundreds of miles to be treated, the cost of freight, not only of the zinc unit, but also of their contained moisture content, must be taken into account.

NICKEL

17. Impala Platinum Refinery, Springs, South Africa

A flotation concentrate is smelted and then leached to recover copper and nickel hydrometallurgically, leaving platinum group metals, primarily in a sludge of undissolved metals.

The acidic process solution is submitted to a variety of processes for nickel and copper recovery and, in the final step, is neutralized to settle gypsum leaving an effluent solution that can be discharged or recycled. Randol Internationa Ltd. did not investigate details of any processes relating to platinum recovery operations as these are considered company confidential.

It is, however, believed that the gypsum precipitate so generated contains enough nickel values for it to be recycled back to the leaching step for incremental recovery.

18. Falconbridge Limited, Falconbridge, Ontario

At Falconbridge, Ontario, plant runoff water from the smelter and mill area was, for years, collected in a small shallow lake area alongside the plantsite where it was decanted to discharge water as an effluent with the mill tailings effluents that, in turn, discharged to the lake and river system. After many years, it was found that potable wellwater from a nearby well contained levels of nickel and other base metals. It was found that solids settling from plant runoff water contained relatively high metal values which had built up as a sediment in the impoundment. When these started to oxidize, base metals were leaking into the aquifer from which potable water was being pumped.

Falconbridge reclaimed the sediments, which were high enough in metal values to justify adding them to feed to the mill to benefit from recovery of incremental values to the tune of $1.5 million.

BASE METALS

18. Piccalinna (Sardinia) Mine

GHIANI and TONETTI (1983) described the treatment of acid mine drainage from the Piccalinna Mine in Sardinia and the recovery of separated metals. Unfortunately, a copy of their paper was not obtained, and no details were obtained.

CYANIDE REAGENT RECOVERY

Several gold ore deposits have not been economically exploitable because the ore contains too much cyanide-soluble copper. When leaching this type of ore, so much copper goes into solution as to cause metallurgical problems and to require such large quantities of cyanide reagent addition that the gold recovery process is made uneconomical.

Although, many years ago, a cyanide recovery process was employed by the Hudson Bay Mining and Smelting Company at Flin Flon, Manitoba, no such operations have been identified in recent times. The Flin Flon process involved acidification of the effluent to volatilize HCN gas which was then redissolved into an alkaline solution for reuse.

Recently, a process has been announced for the recovery of cyanide reagent from effluents containing quantities of cyanide associated with base metals to the extent of being significant to the economics of the operation.

Details of the cyanide recovery process have not yet been released, but they have been promised for RANDOL (1985). The process, when treating tailings solution from an ore requiring 11 Kg NaCN/ton, was said by BERGMAN, et al. (1984) to cost $1.00/ton for cyanide recovery. The BERGMAN, et al. (1984) is inserted into Chapter 40 on cyanide treatment.

INTRODUCTION

Scale, corrosion, and abrasion can directly and indirectly account for surprisingly large expenditures on mine-mill complexes. The full extent of these costs are not always recognized by an operator as they are paid for from different departments under headings such as reagents, maintenance, replacement parts, pipes, pumps, water treatment, service supplies, etc. MOKKEN (1964) used a systems approach to evaluate the cost of pipe, pump, and valve replacement on Witwatersrand gold mines. His estimate of replacements in this area exceeds the total cost of milling and extraction. Much of these replacement costs are the result of corrosion which is directly attributable to water quality and abrasion. Scale control incurs direct costs for scale-inhibiting chemicals and physical scale removal measures. The indirect cost of scale includes the reduction in capacity due to reduced flow rates in pumps and pipes affected and in replacement and maintenance costs.

Water is recycled to an increasing degree as a means of reducing net water consumption and/or reducing the volume of effluents to be discharged or treated, and this trend will continue well into the future. As this occurs, scale and corrosion effects will become even more noticable, and increasingly costly measures will be required to counteract or control them. In addition, those that build up the knowledge and experience to predict and reduce these effects in advance will save costs and headaches as well as achieving a more efficient operation with less expensive downtime.

This investigation was able to carry out only a partial industry survey of water treatment chemicals used in mines and mills. Despite an effort to do so, it failed to establish definitive data on what the range in annual costs for water treatment chemicals and services at mines and mills actually amounts to. The results of a survey of copper, copper-moly, and gold and silver recovery operations is shown in the tables below. The impression gained is that the total cost of scale and corrosion inhibitors varies greatly but can be significant. On the other hand, some very large operations that recycle as much water as they can and are zero discharge, such as Vaal Reefs Exploration and Mining, do not need any scale-inhibiting chemicals in their gold metallurgical processes. Large copper and copper-moly mills employ water treatment service companies to prevent scale and control corrosion in their boilers and elsewhere.

Mining and milling companies would be well advised to survey their expenditures on this type of service and on water treatment chemical purchases throughout their operations. Once it is known how much is spent in this area and the extent to which pumps, parts, pipes, valves, etc. are replaced due to scale and corrosion effects, then they can draw some conclusions and set goals as follows:

- Should more or less attention be given to scale and corrosion control?
- Is the amount spent in this area large enough to justify investing in research and development into fundamental aspects of the phenomena to provide in-house services and expertise aimed at reducing overall costs?
- Are the answers to be found in material selection, water treatment, or both?

SCALE INHIBITION

One way to reduce scale problems is to use a plastic pipeline with a smooth inner surface, e.g., HD polyethylene, but this does not always work. In one case, a flexible rubber pipeline was being tested as it allowed scale to be easily removed after it had formed by simply driving a pickup truck over the line. In another case, a HDPE pipe was suspended across support towers and as it expands and contracts with temperature differences, the scale layer breaks loose due to the flexing motion.

Two innovative ways of reducing scale problems in metallurgical plants that use recycle solutions were identified. The first involves how fresh water is added to the circuit. Metallurgists have observed that, quite often, scale forms locally near the point at which fresh water is added to the circuit. The logical approach, therefore, has been to add fresh water to recycled mill solution in a separate tank or pond allowing it to precipitate species therethat would otherwise have formed scale in the plant. Some operations allow their process water to age for some time after adding fresh water. Examples of such operations include Cities Service, Pinto Valley; Cyprus Bagdad; Cyprus Pima; and Pinson Mining Company, and scale inhibitors are not needed as a result or are needed much more selectively.

A second approach to scale reduction involves an understanding and manipulation of the bicarbonate-carbonate equilibrium and its pH dependence. If, through CO_2 dissolution or any other cause there are bicarbonates present in recycled solution, then when lime is added to raise the pH, the $CaCO_3$ formed may far exceed its solubility at that pH. Even if NaOH is added for pH adjustment, $CaCO_3$ in solution may still be precipitated because at high pH, its solubility is much lower than at a low pH. At Bethlehem Steel Corp.'s Panther Valley Division, thorough aeration has been found to remove much of the CO_2 from solution resulting in less reagent requirement to raise the pH and much smaller quantities of precipitate to handle, i.e., a correspondingly less scaling water quality.

PHYSICAL SCALE REMOVAL

One way that is frequently employed to remove scale from the inside of pipelines is by passing a plastic "pig" through the pipeline, which has an abrasive carborundum coating which literally scours the scale from the inner surface of the pipe. This pigs vary in size up to 26" in diameter. A "crisscross" coated pig 26"Ø costs around R750 (U.S. $375), and a hand-made pig with a wire brush coating costs R1,000 ($500). These are supplied with launchers equipment or as a custom pipecleaning service by:

At Delta Managanese, steel pipes are beaten with sledgehammers by a crew that works full-time to dislodge scale from pipes. At Zincor, steel pipes used to be burnt in an outdoor fire in which the rubber lining is burnt away to release scale which then slides out of the pipes. Delta Managanese had considered using scale inhibitor chemicals but were not sure of the effect that these might have on their electrolytic manganese recovery process.

Brunswick Mining was experimenting with a very flexible pipeline in which scale could be dislodged and broken into pieces by simply driving a pickup truck over it. More information on this experiment would be available from:

SCALE CONTROL

In the course of this investigation, it was found that scale and corrosion control services and reagents are widely used in metallurgical operations. For example, virtually every gold heap leaching and several successful CIP plants for gold recovery use a scale control additive to reduce carbon fouling which, in turn, enhances the efficiency of gold adsorption.

Carbon fouling in columns and CIP tanks generally seems to involve a carbonate scale, and acid washing of carbon is standard practice as a means of removing scale that blocks the carbon pores. For this, nitric or hydrochloric acid are used.

CALGON CORPORATION and NALCO have both recently completed studies on the fouling of carbon by scale in carbon columns and CIP tanks and now are in a position to make advanced scale inhibition recommendations.

Mining and Mineral Processing Research

The formation of calcite scale occurs as a series of aqueous chemical reactions, ultimately leading to the precipitation and deposition of calcium carbonate under alkaline conditions. The process can be likened to any other crystalization from solution in that it initially involves nucleation to form fine seed crystals followed by crystal growth, agglomeration processes, and in this case, deposition on surfaces. These processes can be altered by certain chemical additives which either inhibit nucleation, modify crystal structure, or both. The result of such chemical addition can be one of complete scale inhibition. As such, aqueous systems can be stabilized with respect to scale formation even though their water chemistries would normally indicate instability.

Scale inhibition can also be used to prevent pipes, pumps, and screens from scaling up. Scale can be a problem in Merrill-Crowe filter screens, in barren lines, in carbon desorption circuit heat exchangers, and at several other points in the circuit. Getting back to the fouling of carbon, one operation of Cambrai Mining Co. in Zimbabwe was unable to achieve even a reasonable gold recovery by CIP because the carbon was severely fouled by a carbonate scale before the gold could load.

In the table below, only three heap leaching operations are listed, and only one of these uses a scale inhibiting chemical. In fact, in informal discussions with many heap leaching operations not listed, most of them rely on some form of scale inhibiting chemical.

The survey of gold and silver recovery operations lists more that do not use reagents than those that do. Those that use no reagents include several that recycle water extensively. It is possible that the quality of available water may have a major effect on scaling.

Operations that treat ores containing sulfide minerals and recycle tailings decant solution invariably find a buildup in sulfates and particularly calcium sulfate, a notorious scale former. Gypsum scale can also be very effectively controlled through the use of chemical additives, one of which, sodium hexameta phosphate, is wellknown. In desalination

Dear Hans:

The problems at the Cambrai Mining Co. in Zimbabive are related to carbonate/sulfate scale being deposited in the carbon pores.

Calgon has scale inhibitor treatments capable of controlling these deposits. Two that are most appropriate for gold mine circuits are SCM105 and SCM205.

I have contacted our subsidiary Floccotan (Pty) Ltd. in South Africa about this problem. They will pursue this matter with your friend Ron Edington. Our representative is:

Mr. James Smith
Floccotan (Pty) Ltd.

Let me know if I could be of anymore assistance.

Very truly yours,

CALGON CORPORATION

Ben

B. P. Boffardi, Ph.D
Senior Research Associate

/tt

processes, it is claimed that fouling can be prevented on surfaces in contact with solutions that contain gypsum up to 3-4 times saturation.

An operation that has experienced severe gypsum scale problems in monitor water pipelines is ERGO (East Rand Gold and Uranium Company) on the Witwatersrand which reclaims old gold mine tailings for recovery of pyrite containing gold and uranium by flotation followed by uranium leaching by sulfuric acid. A new CIP plant to treat the entire 1,600,000 tons per month of feed material has been installed. The partly oxidized sulfide-containing tailings material and sulfuric acid used in the process, as well as high TDS minewater used in the process, result in a high $CaSO_4$ level in recycled process water, but surprisingly, little scale problem is encountered in the tailings return solution lines, although serious scaling occurs in the lines taking water to the monitor stations where tailings are repupled. Several scale inhibiting chemicals were being tested at the time of the 1984 visit. Of particular interest is a dynamic scale monitoring device developed by CALGON CORP., whose address was shown above, and supplied in South Africa through their local agents:

FLOCCATAN PTY LTD.
Post Office Box 4578
Randburg 2125
South Africa
(011) 789-3823
Telex: 4-26994
Jack Hallows

This dynamic scale monitor allows scale inhibiting chemicals to be screened and also for dosages to be optimized for a given process solution.

Copper and copper-molybdenum mills in the desert southwest of the U.S.A. recycle tailings water extensively as a water-saving measure. These operations make extensive use of scale control chemicals, and some apply an innovative way of blending fresh water with recycle solution to reduce scale by allowing a precipitate to form and settle outside the plant.

Many mines and mills operate boilers to generate steam and heat. In boilers as in cooling plants, scale inhibition is essential to preserve the efficiency of heat exchanger surfaces lest their performance drops below design resulting in adverse process effects or equipment damage. Once again, the addition of chemicals is a common way of controlling scale in this area. Another way is to use demineralized water as boiler feed water, which is an application for R.O. and ion exchange.

Most typical scale encountered in metallurgical circuits is composed primarily of carbonates and sulfates, usually of calcium although scale can also contain a wide range of other species including magnesium, silica, iron, manganese, aluminum, etc. Bacterial scale

depositions akin to jarosites may be rich in metals and can lead to enhanced localized corrosion due to electrolytic effects.

Scale may be quite soft and easily removed as long as it is submerged. After exposure to the air, it can become very hard and difficult to remove. Sometimes this results in severe scale difficulties at the waterline in tanks, thickeners, etc.

$CaSO_4$ scale has been a problem, particularly where sulfide-containing tailings are involved or where sulfuric acid is used as a reagent and where the ore contains soluble calcium or where lime is used to neutralize tailings. Gypsum scale is commonly inhibited using chemical additives such as NL Baroid Division's S35 which is a hexa-meta phosphate. In operating plants, gypsum scale quite often is enhanced where there are local hot spots, e.g., in heat exchangers. In evaporative desalination, for example, temperatures of solution are sometimes kept below 80°C, above which gypsum seems to be particularly unstable.

It is of interest that if an excessive dose of sodium hexa-meta phosphate is used, then the excess converts to orthophosphate which may then exceed effluent limits. Also, excess Na hexameta phosphate itself converts to orthophosphate which results in phosphate scale formation under certain conditions, so it must be carefully dosed.

Two other operations that experience excessive gypsum scale problems include Delta Manganese Co. and Zinc Corporation of South Africa Ltd., both of which use sulfuric acid as a lixiviant for manganese and zinc leaching respectively. These operations are discussed in Appendix I. In both cases, sodium hexa-meta phosphate might prove useful in modifying the gypsum scale, but concern has been expressed as to the possible effects in their electrolytic cellhouse.

In general, where gypsum scale occurs, sodium hexa-meta phosphate is often applied to inhibit it. Where the scale is a carbonate, then maleic acid derivatives or polyacrylates can be applied. Just 2 ppm of a low molecular weight polyacrylate is found to be effective at inhibiting calcium carbonate scale as it has a marked effect on the $CaCO_3$ crystal structure. Suppliers of polyacrylates are the Nalco Chemical Co., Allied Colloids, and American Cyanamid. In Canada, a company called Alkaril Chemicals Ltd. also manufactures polyacrylates. Polyacrylates are potentially much less expensive to make than the maleic acid derivatives. Phosphonates inhibit both gypsum and $CaCO_3$ scale. WIECHERS (1975) discussed some of the scale inhibiting principles.

A variety of scale inhibiting chemicals are offered to the mining industry by:

TESTING THE EFFECTIVENESS OF SCALE INHIBITION

Drew Industrial Division has developed a simple, yet effective means to test the effectiveness of scale inhibitors in recovery circuits. This method further enhances the data collected by the "PULSE" dynamic scale monitoring unit which produces data on a continuous basis. The combination of these two approaches further ensures up-to-the-minute evaluation of scale deposition in pipelines, pumps, and other water-related equipment.

This device, used by Drew Industrial Division consists of a retractable scale coupon which can be inserted into any system through a valve. Visual examination of this scale coupon can be accomplished in minutes.

Scale deposition can then be noted on the coupon to evaluate the effectiveness of the scale inhibitor in the system. This method can be used continuously to compare various products and/or dosage levels.

The advantage of the retractable probe lies in its simplicity, ease of use and reliability for measuring scale deposition visually in metallurgical and water treatment plants.

Reagents come across in the course of this investigation which are used as dispersants include:

NL Industries, Bariod Division	S-35 Hexa-meta Phosphate
Drew Chemicals	Millsperse 802 Maleic Acid Derivative
Nalco	Nalco 8830
Alchem	Alchem 961
Allied Colloids SA	Antiprex
Anikem (Pty) Ltd.	Anikem 4393
	Anikem 7311 (For Compressor Coolers)
Floccotan	CL 4000
Ferste Chemicals	PC 40
Alkaril Chemicals Ltd.	Polyacrylates

Most of the copper and copper-molybdenum mills surveyed in the U.S.A. use recycle water. When recycled water is used, scale inhibitors of one kind or another are often applied, for example:

Operation	Treatment of Reclaim Solution (1980)
ASARCO, Sacaton	Hexametaphosphate for Scale Control
Phelps Dodge, Metcalf	Hexametaphosphate for Scale Control; Lime for pH Contol
Phelps Dodge, Morenci	Hexametaphosphate
Phelps Dodge, New Cornelia	Drew Co. "Amitrol"
Phelps Dodge, Tyrone	Calgon CL-50 (Inorganic Phosphate) and CL-95 (Dispersant), 5:1 Radio for Scale Control
Inspiration, Christmas	Calgon Reagents for Scale Control
Cities Service, Pinto Valley	Discharge water is put in a holding tank, and fresh water is added. Salts are allowed to settle out before water is recycled. No reagents are used.

Anaconda Co., Carr Fork, UT	Recycled water is not chemically treated.
Magma, Superior	Phosphate chemicals are added for scale control.
Anaconda, Butte, MT	Minewater and precipitation plant (lime) overflow is added to mill tailings underflow. Heavy metals from mine and precipitation plants waters are precipitated by alkaline mill tailings underflow. Tailings dam water is returned to plant at pH 10.5.
ASARCO, Mission	P_2O_5 Scale Control Additive Used
ASARCO, Silver Bell	Phosphate Chemical for Scale Control
Cyprus, Bagdad	Fresh water is added to recycle water in a tank and settled; no chemcals are used for scale control.
Cyprus, Pima	Tailings pond decant is mixed with fresh water. A precpitate is allowed to settle out. No chemcals are used.
Inspiration Copper, Inspiration	Decant from tailings pond is mixed with fresh water, and a Calgon reagent is added and the water recycled.
AMAX, Twin Buttes	NL Baroid chemical is added for scale control.
Duval, Sierrita and Esperanza	Mill tailings are thickened, and the overflow is stored in a reclaim water reservoir. Tailings pond decant solution is pumped to the reclaim water reservoir. Reclaim water reservoir is thickened, and overflow is recycled to the plant. A phosphate-based additive supplied by NL Baroid Div. is added for scale control.
Duval Corp.	Overflow from tailings thickeners is recycled to the plant with tailings pond decant. Water is chlorinated quarterly to kill bacteria.
Black Mountain, South Africa (Cu, Pb, Zn, Ag Flotation)	No Scale Inhibitors Used

SCALE CONTROL IN GOLD AND SILVER RECOVERY OPERATIONS

A recent survey of gold and silver recovery operations included questions as to the amount and type of scale inhibiting reagents used and where they are applied in the circuit. Responses to this questionaire are summarized as follows:

SCALE CONTROL IN GOLD AND SILVER RECOVERY OPERATIONS

Operation	Type	Location	Scale Inhibitor Used	Where Used	Dosage	Comments
Whim Creek Consolidated NL	HL, Au	Western Australia	Nil	N/A	N/A	$NaOH/Na_2CO_3$ Used for pH Adjustment

CORROSION

There are several mechanisms by which corrosion of metal pipes, structures, valves, and equipment can occur in mine-mill operations. These were described by BOFFARDI (1984) in a fascinating description, unfortunately not available in printed form. NALCO (1979) outlines some of the same aspects and shows some ways to control corrosion. Clearly, corrosion control is an art based on years of experience as well as a science. As solutions are recycled, this can result in a gradual increase in ionic species which cause an enhanced rate of corrosion. One of the most common of these is the chloride ion which, in an acid medium, corrodes carbon steel and even most stainless steels. Internal screens fabricated from stainless steel were corroded very rapidly in an ion exchange plant installed on the Witwatersrand. This corrosion was blamed on the presence of thiosulfate in the pregnant solution.

Corrosion of stainless steel autoclaves installed at Rustenburg Refiners to leach a base metal matte under pressure became a problem when the chloride level in the regional water supply started to rise during a drought. These metallurgical solutions are recycled extensively, and any chloride introduced in feedwater accumulates in the system. At Rössing Uranium Ltd., and Quivira Mining Co. uranium mills in Namibia and New Mexico, the extent to which acid tailings dam reclaim solution can be recycled to the mills is limited by corrosion of thickener rakes in the CCD circuit.

This corrosion is caused by chloride levels in the acid pulp solutions. In the case of Rössing, the need to increase the use of recycle solution was important enough to justify applying polyurethane coating to thickener rakes and the fabrication of stainless steel pump shaft sleeves to allow recycled water to be used in their lubrication. These measures and details are provided in the trip report on Rössing Uranium Ltd. in Appendix I. To date, the following suppliers and appliers of polyurethane coatings have been identified:

UNIROYAL INTERNATIONAL, INC.
World Headquarters
Middlebury, CT 06749

Ian Lyon
Managing Director

The cost of applying polyurethane coatings in South Africa works out to about R20 per mm/m² or R60 per m² for a 3 mm application. Polyurethane is much faster to apply than is rubber. Both require spark testing of coated surfaces prior to use.

At the Kloof Gold Mine, about 50 kilometers of underground piping reputedly had to be replaced due to corrosion that was enhanced by the presence of Cl^- in minewater.

Pitting corrosion is caused by galvanic effects and can be very rapid. Recycle of water results in a buildup of nutrients and metals and especially in an acid media, bacterial populations may thrive. At Rössing Uranium Ltd., when the use of recycled tailings water was increased, a biologically deposited "jarosite" scale containing relatively high concentrations of base metals was found to accummulate on the inner surface of steel pipes. Enhanced corrosion of the steel occurred under the scale layers due to an emf difference between the scale and the pipesteel. This is an example of a case where corrosion is enhanced by scale formation and where the use of an appropriate biocide would prevent both from occurring. A similar type of biological scale with high metal levels was observed at Bethlehem Steel Corp.'s Panther Valley Division coal mine in Pennsylvania in a pump used to lift minewater to the surface. Presumably, high density polyurethane pipelines resist this type of corrosion, although cement lines have been known to be attacked.

At Venterspost Gold Mining Co. Ltd. on the Witwatersrand, a steel pipeline is used to transport water pumped from the regional aquifer to a point at which it is reinjected 12 km away. This water was extremely corrosive, and the problem was solved simply by adding a small amount of lime to the water which rendered it slightly scaling.

It is wellknown that chloride ions in water result in enhanced corrosion of both mild and stainless steel. Another less wellknown cause of corrosion, especially when heated, is fluoride. Apparently, just a few ppm of Fluoride can be very damaging. More information on details of fluoride corrosion effects would be available from:

DETERMINATION OF CORROSIVITY

There are innovative ways to determine the corrosivity of water. One way is to analyze the water and to compute the corrosivity or scaling nature of water. There are several indices that are in use including the commonly used Langelier Index. Corrosiveness can also be measured using a variety of tests in the laboratoy. Dynamic corrosivity measuring devices are available from U.S. suppliers and consultants such as:

E, G & G PRINCETON APPLIED RESEARCH
Post Office Box 2565
Princeton, NJ 08540
(609) 452-2111

In general, corrosion can be avoided by appropriate use of materials of construction and coatings, and it is customary to have consulting engineers with specialized corrosion experience to survey the process and to advise on material selection. Although this approach is invaluable when corrosive solutions are to be used, it requires that the composition of solutions be known in advance. This, in turn, requires accurate salt balance modelling which, for most mine-mill complexes, is still an inexact science. Some idea can be gained from tests and analyses of the ore, a knowledge of the reagents to be used, and proposed operating pH to determine what corrosion phenomena may be expected. Some companies have more experience in water and salt balance modelling than others.

Calgon Corporation has developed a very effective computerized simulator for cooling water system performance prediction for electric power plants. This program uses a huge database of empirical data gathered from operating power plants all over the world. This program and database, called "Calguard," cost many millions of dollars and years of work to develop, and it relates primarily to power plant water cooling systems. This sytem is capable of reproducing the operating conditions of cooling water systems and diagnosing the problems which will be encountered from corrosion, scale, and deposition. The entire range of treatment options can be scanned and the results accurately predicted. Since the computer simulator is based on fundamental technology, it applies to both present and future cooling system requirements. This represents a capability that is dramatically distinct from data banks which rely entirely on past experiences to address present day needs. Although no similar system exists for mine-mill water systems, the approach applied in developing the Calguard program as described by BOFFARDI and SCHWEITZER (?) could be helpful to those wishing to attempt the task of developing one. More information on Calguard can be requested from:

Michael A. Brett

Desalination processes are increasingly being used to produce low TDS water for use as boiler feed, battery water, and even potable water. These processes include ion exchange, reverse osmosis, electrodialysis, and evaporation. Desalinated water with very low TDS levels is one of the most corrosive of all water, and a post treatment is necessary to prevent damage to pipes, pumps, tanks, and reticulation systems. Usually these involve contacting water with granular limestone.

Corrosion of cooling tubes in refrigeration plants at large mine-mill complexes has been associated with the presence of high Cl^- and $SO_4^=$ as well as ammonia in cooling water. This is one reason that reclaimed sewage water may not be desirable for use in cooling systems. However, Calgon Corp. offers an additive which they find inhibits corrosion of copper-nickel cooling tubes exposed to this kind of water. Enquiries can be directed to Bennett Boffardi at the Calgon address shown above. Elsewhere, corrosion studies conducted at the CSIR recommended a different metal alloy for use in cooling tubes exposed to this kind of water. An alternative is to employ a sewage treatment process that removes ammonia very efficiently.

CORROSION PREVENTION

As with scale, corrosion can be controlled by selecting non-corrosive materials. For example, stainless steel may be more corrosive resistant than mild steel, but it is also more expensive.

The mid-1980's sees the dawning of the age of plastics of which there is a wide range for use either for fabrication of corrosion and abrasion resistant components or coatings. There are two aspects to corrosion resistant materials--first are the suppliers of the resins, etc., and developers of the materials such as DuPont, Uniroyal, etc. Usually, however, the mining company will be exposed to these materials through fabricators who manufacture plastic components and through service companies that offer to apply plastics.

Of course, one wellknown example of this is DuPont's high density polyethylene pipe known as Schlairpipe. Since it first became available less than a decade ago, a whole range of manufacturers and vendors have sprung up offering similar products.

On the Witwatersrand, for example, underground minewater after removal of suspended solids is treated with lime before it is pumped to the surface. This measure is adopted to minimize corrosion of pipes and pumps.

Belt filtration facilities are characterized by a lot of splash which creates a highly corrosive environment when corrosive solutions are used. Some belt filters have been constructed of stainless steel; others have been very carefully coated with plastics, e.g. epoxy coal tar or polyurethane. Where decks are employed in this type of environment, the use of conventional steel grating is asking for high maintenance needs. Consequently, this is one area where fiberglass grating, although initially more expensive, is likely to pay for itself over a short period of time.

Today, ceramic and plastic equipment items such as cyclones, valves, solution distributors, etc. are being used with increasing frequency. Suppliers include:

CORROSION CONTROL

Principle means of corrosion control that can be applied if it is not possible to select a non-corroding material include the following:

Insulation

The joining of dissimilar metals can lead to galvanic corrosion. If it is essential to use dissimilar materials, they should be insulated from one another. This can be accomplished by inserting non-conductive materials (such as plastic pipe) between them. When this is done, it may be necessary to put an electrical cable as a jumper around the isolated unit because the system may be used as an electrical ground.

Applied Chemical Inhibitors

In spite of the fact that many options exist to minimize corrosion by improved design or better construction methods, because of economics, the majority of systems are designed and fabricated in such a way that a chemical inhibitor program is needed to control corrosion. This applies to all types of water systems: potable water distribution systems, cooling water systems, boiler water systems, process water, and effluent treatment plants.

Corrosion inhibitors are commonly used in cooling water systems. Just as corrosion can be inhibited by interrupting either the anodic or the cathodic reactions, so any chemical applied to the water to stop the anodic reaction will stop corrosion. Any material that is added to reduce the rate controlling cathodic reaction will reduce corrosion. An effective corrosion control program usually depends on specific inhibitors to stop the anodic reaction, slow the cathodic reaction, or both. Typical inhibitors in use are:

Principally Anodic	Principally Cathodic	Both Anodic and Cathodic
Chromate	Calcium Carbonate	Organic Filming Amines
Orthophosphate	Polyphosphonate	
Nitrate	Zinc	
Silicate		

Of the anodic inhibitors, chromate is widely used and is a very strong inhibitor. Where many common corrosion inhibitors form a barrier layer on the metal surface, chromate reacts with the metal forming a hard layer of reduced chromate Cr_2O_3 and alpha iron.

Orthophosphate also forms a phosphate film, but it is not as tightly adherent or as long lasting as chromate. Ordinarily nitrate, orthophosphate, and silicate are less often used than chromate in open recirculating cooling systems because of costs and technical limitations, including the potential for deposits (tricalcium phosphate), nutrient effect on microbes, and limited effectiveness. Chromate, on the other hand, is considered environmentally very undesirable which has resulted in corrosion control formulations with lower $Cr^{(VI)}$ content.

Anodic inhibitors also carry risk: If applied in insufficient quantities, they do not properly passivate all anodic sites. Under these circumstances, the few remaining sites become the focal point of all the electron flow to the cathodic reaction area, and deep pitting can result. Therefore, it is important to maintain sufficient quantities of anodic inhibitor at all times.

Cathodic inhibitors generally reduce the corrosion rate by forming a barrier or film at the cathode, restricting the hydrogen ion or oxygen migration to the cathodic surface to complete the corrosion reaction. Overall rate of corrosion is under cathodic control so the corrosion rate is reduced proportionally to the reduction in cathodic surface area. Cathodic species zinc, polyphosphate, and calcium carbonate are all considered safe compared to the risks of anodic inhibitors.

ANODIC/CATHODIC INHIBITOR MIXTURES

Some inhibitors enhance the activity of others. By itself, 200-300 mg/l CrO_4 is needed to prevent corrosion in an open recirculating cooling system. However, when combined with zinc, various organic and inorganic phosphates or molybdates, equal or better results are achieved with 20-30 mg/l CrO_4. Some systems are effective at controlling corrosion with only 10 mg/l CrO_4.

ORGANIC FILMS

These materials form filming layers on metal surfaces to separate the water and metal. These include filming amines that work effectively only in significantly reduced oxygen environments. Copper and copper alloy corrosion is reduced by applying inhibitors mercapto benzo thiazole, benzotriazole, and olytriazole. Certain organo-phosphorous scale inhibitors used in cooling systems are aggressive to copper-type materials so the addition of a copper inhibitor film must be used when they are applied.

SACRIFICIAL ANODES

Sacrificial anodes reduce galvanic attack by providing a metal (usually zinc or magnesium) that is higher in the galvanic series than either of the coupled metals. The sacrificial anode becomes anodic to both metals and supplies electrons to these cathodic surfaces. Design and placement of these anodes is a science in itself.

BIOCIDES

Use of appropriate biocides removes bacteria that adhere to the wall of pipes, etc. and deposit metal layers under a layer of scale. The biologically deposited metal then forms a galvanic electrode in the corrosion process which results in corrosion unless the bacteria that deposit the scale can be prevented from acting.

MONITORING CORROSION

Most metallurgical systems are in continuous use so it is rare to be able to inspect the actual system to observe or to measure corrosion and corrosion inhibition. A number of tools have been developed to measure corrosion indirectly.

Corrosion Coupons: These preweighed metal samples are normally inserted into the system for 30-90 days. Following removal, they are cleaned and reweighed. The metal loss and type of attack is determined and reported.

Corrosion Nipples: Corrosion nipples are only visually inspected. A nipple consists of a single pipe that is installed in a bypass arrangement so that the nipple can easily be removed for inspection at any time.

Corrosion Meters: Corrosion meters provide long-term data. More immediate results are possible after 24 hours or less following the initial system insertion. The meter works by measuring an electrical potential across electrodes made of the metal being evaluated. The corrosion meter, once stabilized, can provide instantaneous corrosion reading which are useful for optimizing pH, TDS, inhibitor level, chlorine addition, and other control variables.

ABRASION

Abrasion is usually caused in pumps, pipes, etc. on account of the suspension of abrasive solids in water that is pumped through them.

On the Witwatersrand, underground minewater is first allowed to settle with the aid of flocculants as described in Chapter 12 on the removal of suspended solids. Once most of the suspended solids have been separated into a sludge, this water can be pumped to the surface with much less abrasion damage. To achieve this, several innovative devices have been designed and tested on a commercial scale and found to work satisfactorily.

Also, on the Witwatersrand, a new type of hydraulic power using water to power tools and equipment as opposed to organic hydraulic fluids or air in tools that are currently pneumatically powered. If water is to be used, it will be critical to remove fine suspended silica from the water used for this purpose, lest it cause abrasion wear of the hydraulic components. It is not known what the constraints on the hydraulic fluids are as far as suspended solids are concerned. In due course, information will be released by:

THE CHAMBER OF MINES RESEARCH

Coors makes wear resitable components from alumina ceramics and also from wear resistant silicon carbide. Claims of outlasting ni-hard steel by 10 times at a cost premium of 30-40% are being made.

Even in carbon steel piplines, a way has been found to make pipe bends and fittings very much harder through a unique induction heat treating process to form a uniform hardened layer at the inner pipe wall at 600 Brinell hardness. The unhardened outer layer at 250

Brinell hardness ensures that the pipe has the strength and ductility required in typical pipe service. This type of pipe is available along with an innovative way to bend pipe using induction heating from:

POLYURETHANE COATINGS

Polyurethane coating are available from the same suppliers as were listed in the previous section on corrosion protection.

SPECIALTY ABRASION RESISTANT PLASTIC APPLICATIONS

Where recycle water containing fine solids particles is used, for example, in pump shaft lubrication as at Rössing Uranium or other such corrosive/abrasive applications, e.g., cloth roller bearings on belt filters, the need arises for specialty plastic components. One highly innovative company that formulates plastics and fabricates components to test or on small run production basis is:

Morganite®

WEAR CONTROL CERAMICS

MORBLOCK™

PIPE LINERS

CUSTOM SHAPES

TONGUE & GROOVE LINING BLOCK

MORHEX™

MORCAST™

A complete line of cost-efficient high alumina ceramic linings which extend the productive life of a wide variety of bulk material handling and processing equipment. Ceramic linings reduce downtime and the frequent repairs resulting from premature wear or destruction from abrasion, chemical degradation, temperature extremes, impact, pressure and other hostile operating or environmental conditions.

Ceramic Products

Morganite® Alumina Ceramics

General Characteristics of MORGANITE Alumina

Sapphire-Hard: 9 on the Mohs Hardness Scale; second only to diamonds in hardness among natural materials.

Extremely Abrasion Resistant in a wide variety of material-handling environments.

Temperature Tolerant: Maintains wear-resistant qualities and dimensional stability at temperatures from -50 to + 2000F with good thermal shock resistance. By comparison, rubber linings decompose at temperatures above 200F; steel's resistance to wear and oxidation decreases as temperatures increase.

Resists Acids, Chemicals: Can be used in contact with most alkalies or mineral acids, except hydrofluoric. Resists attack by hydrocarbons and other corrosives.

Resists Pressure to 250,000 psi: The combination of high hardness and density gives MORGANITE high alumina exceptional compressive strength.

Inert: Alumina Ceramic is non-toxic, non-allergenic, and is non-hazardous to persons or the environment.

Non-contaminating: Alumina Ceramic is non-toxic, non-contaminating, won't rust, oxidize, discolor or decompose.

Morcast™

A mixture of 88 to 94% Grade, crushed aluminia ceramic, suspended in an epoxy resin designed to maximize bond strength to various substrates and the aluminia ceramic.

MORCAST ceramics adhere to most clean, dry surfaces including metal, ceramic, plaster, wood and cement and offers high impact resistance.

Spread coats can be applied in thicknesses from 1/16" to 1" or more with little or no sag or slumping.

MORCAST ceramics are available in three grades:

MORCAST HT:	For on site application to horizontal surfaces
MORCAST VT:	For on site application to vertical surfaces
MORCAST C:	For application to substrates by Morganite or specialty casted shapes (shop applied)

Working time is thirty minutes. Curing time is approximately eight hours at 70F. Maximum use temperature is 375F. Our 20 lb. kit covers 5 square feet to 1/4" thickness. Shelf life up to one year.

Comparative Properties of MORGANITE High Alumina Ceramic

The important properties of MORGANITE Ceramics are summarized in the table below. A range of values is listed for material classifications. Additional data may be obtained from Morganite Canada Inc. upon request.

PROPERTY		MORGANITE MATERIAL NUMBER	
		M[illegible]	M[illegible]
Alumina Content, Nominally	Al_2O_3%	87	94
Tensile Strength	Kg/cm²	1,265	1,800
	PSI	18,000	25,000
Compressive Strength	Kg/cm²	16,500	21,100
	PSI	235,000	300,000
Modulus of Elasticity	Kg/cm²	2.25×10^6	3×10^6
	PSI	32×10^6	43×10^6
Flexural Strength	Kg/cm²	2,990	3,160
	PSI	42,500	45,000
Impact Resistance, Charpy		6.3-6.5	6.5-7
Specific Gravity, Apparent		3.48	3.64
Porosity, Helium Mass Spectrometer		Gas Tight	Gas Tight
Water Absorption		0	0
Thermal Conductivity cal/sec/cm²/cm/°C @ 25°C		.03-.04	.05-.053
Average Coefficient of Thermal Expansion cm/cm/°C	25/200° 25/500° 25/700°	6.2×10^{-6} 7.09×10^{-6} 7.55×10^{-6}	5.5×10^{-6} 7.6×10^{-6} 7.9×10^{-6}
Hardness, Mohs Scale		9+	9+
Thermal Shock Resistance*		Good	Good
Firing Temperature, °C		1520	1675

* This quality affected by the size and contour of the part.

All data tests completed to ASTM Standards. Results are average for specimen tested and should be — but are not guaranteed to be — applicable to parts made of the material. Tests made on manufactured parts might vary slightly higher or slightly lower.

Packaging: Carton size: 6½" x 13" x 4". Approximate weight of packed carton is 35 pounds. Bulk packing on pallets available. Approximate pallet weight is 2500 pounds per pallet.

We invite inquiries for special sizes or configurations. Write or call: Morganite Canada Inc., Abrasion Resistant Materials Division, 3603 - 2nd Street N.E., Calgary, Alberta Canada T2E 3H6. Telephone (403) 230-1817 — Telex: 03-826877.

O.F.S. PIONEERS SAVING MINING INDUSTRY THOUSANDS

By combining their expertise two Free State entrepreneurs made a significant contribution towards underground pump maintenance.

Vesconite packing rings and protection plates fitted to a casing section of a high pressure multi-stage pump

When an 11 stage, 1100 Hp 825 kW underground centrifugal pump runs dry, roughly R25 000 goes down the drain. The resultant pump overall usually requires replacement of impellers, rings, diffusers, balancing disc, stationary disc and shaft.

A Welkom pump engineer, Doug Ray, has managed to bring this cost down to below R2 000 by introducing a packing ring and protection plates developed by South Africa's pioneer of engineering plastics, Alain Leger of Virginia, as a replacement for phosphor bronze parts.

This saving is being accomplished by fitting the multi-stage pumps with components made from Vesconite, a wear resistant thermoplastic polymer, which in the event of the pump running dry prevents metal to metal seizure.

Apart from outlasting similar phosphor bronze components and being resistant to erosion caused by water-borne abrasives, Vesconite melts harmlessly should a pump overheat. Hence it prevents the welding together of expensive metal components and eliminates the need for replacement of many thousands of Rands of spare parts.

The concept of the packing ring made from engineering plastics has been developed during many years of experimentation. Ray, who founded his Welkom pump service company in the late fifties, became increasingly aware of the need for a protection device in centrifugal pumps. He started searching for a material which could absorb the potential damage in a dry pump and initially fitted rings with laminated asbestos. The mud content in the water caused excessive wear and he subsequently tried moulded PTFE rings. However this material has the tendency of absorbing fine grit and consequently wears away the impellers.

Ray presented his problem to Alain Leger of Vesco Plastics in neighbouring Virginia whom he knew had been working for many years developing a thermoplastic polymer which would combine the load bearing capacity of white metal and long life of nylon. The resultant material, Vesconite, today is a sought after material as a replacement for bronze in bearings and bushes carrying high loads with small clearances under dirty, corrosive and poorly lubricated conditions. Its high dimensional stability and low friction coefficient even improve when the thermoplastic is immersed in water.

This was exactly the material Ray was looking for. The Vesconite component was put to the stringent test of lining a stationary disc subject to high velocity and friction. Early tests looked promising and with the co-operation of various engineers in Welkom mines a number of large and small packing rings and protection plates were fitted in a variety of pumps. It soon became apparant that the Vesconite parts would outlast those made from phosphor bronze.

Since 1970 the fitting of Vesconite rings and ceramic coating of the eye and boss of the impeller are standard practice for all pumps passing through the workshops of Rays Pump Service Company. Apart from two instances where a small packing ring failed owing to a large quantity of fine wood in the water, the mines have had most satisfactory results with this engineering plastics material.

The problem of pumps running dry is not only confined to the mining industry in South Africa. It is an international problem with which engineers throughout the world have to contend. This makes the achievement of Leger and Ray so much more remarkable.

Leger feels that the success largely resulted from a combination of Ray's every day involvement in pumping problems and possession of pump technology together with the availability of very large plastic parts in the right material for what was believed to be purely a metal application.

Doug Ray's packing ring development has not been his only engineering achievement. While building up his business as centrifugal pump specialists overhauling multi-stage underground water pumps he found that he had to make innovations all the time. Pumps of this type cannot be out of commission for any length of time and non-availability of parts was the order of the day. This led him to gradually equip his workshop with NC-driven lathes, milling machines, etc. which enable him to manufacture most parts in-

In many respects the workshop is self-sufficient for the provision of spare parts. A double shrouded diffuser cast in the company's own foundry is being jig machined.

house. With the addition recently of a foundry to make pump castings he has created a completely self-sufficient entity.

To minimise delays between breakdown and re-installation Ray has acquired an aircraft which he pilots himself to various mining areas in the Free State, Transvaal and Northern Cape. This means that within a few hours of a breakdown Ray can assess the damage, quote on the job and have one of his vehicles on the way to collect the pump.

Alain Leger's development of thermoplastics makes equally interesting reading. A chemical engineer who, since 1967 was branching out from hardchrome plating into engineering plastics, found that the nylon he was importing did not have the versatility needed for a bearing material. Committing substantial resources from his existing business he started to develop extrusion techniques to produce rod and bushing from various polymers. There was no expertise to draw from either in South Africa or elsewhere. Eventually he found a thermoplastic with excellent dimensional stability and load bearing capabilities together with outstanding friction and wear resistance properties.

Recalls Leger: "Operating from the Free State didn't help either. Being far away from engineering facilities we had to design and produce ourselves, much of the tooling and equipment. In retrospect this isolation probably gave us the opportunity to explore a field which hadn't been tackled before and kindled the determination to succeed."

Initially there was buyer resistance to his new product. People thought of engineering plastics as being a cheap material incapable of accepting loads and of resisting wear or even lubricants. However resistance was gradually overcome as the material proved itself and today Vesconite can be found in heavy vehicles, front-end loaders, ships and in mining equipment.

Leger made considerable investments in plant and machinery to produce thin walled bushing stock and finished components to provide a wide choice of machinable materials to firms with machining facilities or to end users requiring ready to use parts.

Not only is Vesconite recognised as a prime engineering material in South Africa but already 10% of total production is destined for overseas markets, no mean feat for a Free State company.

A display of a number of bronze and stainless steel components manufactured by Ray's Pump Service Company. The gland and throttling sleeves have been ceramic coated.

TAILINGS IMPOUNDMENTS

INTRODUCTION

Tailings impoundment design, installation, and maintenance are a most important integral part of water management in mine-mill complexes and must be considered in any attempt to apply a systems approach.

The objectives of this chapter are to:

1. Provide an insight into the needs of tailings disposal methods within the framework of emerging environmental protection regulations.

2. Emphasize just how great the impact of tailings disposal techniques are on the economics of the mining industry, especially in some climatic regions.

3. Establish goals and objectives for tailings impoundment design to best meet regulatory requirements.

4. Outline several advanced and innovative techniques for tailings disposal which can reduce the overall costs and do a better job taking also into account post-operational requirements.

5. Identify sources of expertise in the technologies involved.

6. Provide some guidelines and identify some pitfalls associated with plastic membrane applications in water impoundments.

IMPORTANCE OF TAILINGS IMPOUNDMENT DESIGN IN THE IMPACT OF MINING AND MILLING ON THE ENVIRONMENT

At startup, that is before a significant volume of tailings have accumulated and while they are still fresh, the impact of tailings impoundments on the quality of water recycled to the mill or discharged to the environment is at first usually negligible. As tailings grow in volume and as they oxidize (especially if they contain sulfide minerals), their impact on water quality increases until the mine is worked out and closes and milling operations cease. Thereafter, the tailings impoundment and old evaporation ponds, wasterock piles, etc. are the main source of pollution from the site and can inflict very serious damage unless properly managed.

Considering that the life of a mine and mill may typically range between 10-50 years, but that the potential for environmental impact from the site exists for centuries thereafter,

the potential impact on the environment from minewaste and mill tailings after a mine shuts down is usually greater even than it is during the life of that mine and mill.

Environmental protection constraints may require that the tailings impoundment be maintained and that seepage and runoff be collected and treated to meet discharge quality criteria "in perpetuity." The cumulative cost of doing so for hundreds of years is awesome; therefore, better ways of disposing of tailings are needed that cost less to maintain and possibly avoid the need for a treatment plant.

What is the nature of the damage caused by tailings and water impoundments on the environment? The answer to this question requires site-specific answers and is not straightforward. Clearly, the impact of tailings will be minimal if the sites are managed and if effluents therefrom are treated before they are discharged. In climates with a net precipitation, the environment is usually different to that in climates with net evaporation. Also, liquid effluents will be generated in excess of evaporation losses, and containment can be an accumulating problem. Tailings containing sulfide minerals will have a different impact to those that do not. In net evaporation climates, tailings can be dewatered or simply allowed to stand and, gradually through evaporation, they will dry out. All that is needed is an impermeable base to contain seepage and a means of preventing erosion as well as collecting runoff. In some cases where geochemical attenuation of dissolved species in soil and rock beneath a tailings pond site occurs, even the impermeable liner may be dispensed with. In net precipitation areas, the installation of an impermeable liner to contain seepage may compound the problem as the volume of water in the impoundment will steadily accumulate.

Unless they are controled, tailings which contain sulfides impact the environment through release of water of low pH due to acid generation and also a variety of dissolved species such as base metals at levels that are toxic to aquatic life or which render groundwater aquifers non-usable as potable water. There are four ways sulfide tailings can impact the environment: Seepage; runoff, airborne dust; and pond failure.

Seepage of tailings pond water or runoff water results in contaminated water getting into groundwater aquifers. In some cases, seepage through an impoundment wall may surface again and get into surface waters, e.g., a stream running alongside the impoundment.

Runoff refers to precipitation on the tailings impoundment itself and also to precipitation draining onto the tailings site from the surrounding area which becomes contaminated as it comes into contact with the surface of the tailings impoundment. Superficial examination would lead to the conclusion that once the surface of dried out tailings has been "washed" through contact with runoff, its salt content would steadily be depleted until it becomes inert. This is not, however, the case as vertical transportation of salts to the surface continues from the pond interior through capillary action. If the tailings are submerged,

KAM KOTIA ABANDONED MILL TAILINGS SITE
TIMMINS, ONTARIO

then ion migration by diffusion occurs from below the solids surface into the surface water.

Airborne dust. When tailings materials are deposited in an impoundment, some configurations call for removal of free liquids by decantation or controlled subsurface drainage or seepage. The dry surface tailings may be subject to a dusting problem as was observed, for example, at an Elliot Lake site. This dust, which contains sulfides if these are present in the tailings material, then gets distributed over a wide area where it rapidly oxidizes and releases acid and metals to surface runoff.

Pond failure. Improper pond construction and inadequate control of the phreatic pressure (water table) inside the pond can result in pond failure. Likewise, in areas with net precipitation, if the pond is impermeable and no provision is made to draw excess water from the pond, liquids will accumulate in the pond until it overflows. Once that happens, erosion of the dam wall may damage it to the extent of impoundment failure. Pond failure, apart from the release of toxic metals and reagents, also causes severe silt damage to the drainage in its path.

GOALS IN TAILINGS IMPOUNDMENT DESIGN

- The impoundment must be strong enough to be physically safe. This is a function of the site and how it is designed and built, which may have to take earthquake probabilities into account.

- It must be affordable.

- It must be large enough to impound all the tailings which it is designed to hold.

- Seepage must be prevented where this is required to protect groundwater quality or to meet environment protection regulations and permit requirement.

- A goal is to find a site where the soils and substrata are already of low permeability or which are able to geochemically attenuate contaminants in seepage so that no additional clay or plastic membrane linings are required.

- The tailings pond may be used as a solution aging and storage impoundment during the life of the operation. It may fulfill a function in overall water conservation.

- In net precipitation areas particularly, the impoundment must be large enough to accommodate a growing water inventory if precipitation exceeds evaporation plus seepage. It may be necessary to draw excess water from the tailings pond for use

particularly useful. Uranium tailing disposal for some reason has been scrutinized more than any other, and these symposia brought together top people in this field. The proceedings are available from:

An excellent review of various techniques of tailings disposal showing how important the management of water becomes, especially in wetter climates, was prepared by CALDWELL and WELSH (1984) from which several illustrations inserted below were taken.

Because tailings disposal holds the key to so many environmental problems, major studies are underway to try and find better techniques. Several of these are group studies, presumably with government and industry funding, and information may be available from:

1) The Canadian uranium industry faces the same problem and has, for several years, also been working on tailings disposal techniques with a research center for the purpose at Elliot Lake. This work has been largely undertaken by:

CANMET

Gordon M. Ritcey

CANMET has also gathered important data on base metal mill tailings disposal, and Gordon Ritcey and M. Silver are intensely interested in this aspect.

in the mill as an auxiliary source of water or for separate disposal by evaporation or for discharge after appropriate treatment.

- The surface of the impoundment must be made stable enough to resist erosion by wind and water.

- On closure, the site must remain stable and measures adopted to preferably inhibit or prevent acid mine drainage. If this is not possible, then the goal must be to provide means to control its impact on the environment.

- The most desirable goal is to be able to abandon the site after completion of the operation in an environmentally acceptable manner requiring no further maintenance and especially avoiding the need for a water treatment plant.

- If the tailings contain low-level resource values which may potentially be recovered profitably in the future, then the tailings impoundment should be such that will allow practical reclamation of the tailings for future processing if and when the need arises.

- The goal of all tailings designs should be to achieve an impoundment requiring a minimum of ongoing maintenance.

SELECTION OF APPROPRIATE TAILINGS DISPOSAL METHOD

In most cases, there are several possible alternative ways in which tailings can be disposed of. There is no clear-cut universally "best" method. Selection of an optimum alternative depends on the topography, geology, location, and climate at the site and the nature of the tailings themselves. It also depends on the naturally available materials for use in impoundment construction and for linings. The usual approach is to retain a firm of expert tailings disposal engineers to survey the possible sites and then to prepare cost evaluations for several alternatives specifically for the operation under consideration.

SOURCES OF INFORMATION ON TAILINGS DISPOSAL

Information on tailings disposal is available in the literature and from the various geotechnical engineering companies that specialize in this field that are listed at the end of this chapter and referred to throughout.

As far as literature sources are concerned, the proceedings of a series of annual symposia on uranium mill tailings management held at the Colorado State University are

ALTERNATIVES FOR TAILINGS DISPOSAL

1) Mine Backfill
2) Above Ground Tailings Ponds with Controlled Release of Liquids
3) Above Ground Tailings Ponds with Impermeable Lining
4) Below Grade Impoundment
5) Combination Above and Below Grade Impoundment
6) Robinsky Thickened Tailings Method
7) "Dry" Tailings Disposal
8) "Semi-Dry" or Subaerial Tailings Disposal
9) Submarine Tailings Disposal
10) Deep Lake Disposal

All of the above alternatives have been applied with several variations. Regulatory requirements, ore characteristics, mill process design, and physical and environmental conditions at each specific disposal site are probably the four most important factors influencing construction and operating costs of modern mill waste disposal facilities. Some comments on each of the alternatives listed above may be in order, particularly as they apply to water management and treatment in mine-mill complexes. These observations are, however, made by an author with limited experience in this field.

Mine Backfill

Underground mine backfill is practised at several operations including Homestake Mining Company at Creede, Colorado, and Lead, South Dakota; The Black Mountain Mineral Development Co. at Aggeneys, South Africa; Kidd Creek Mines, Timmins, Ontario; Noranda Geco Division, Ontario, and many more.

the way backfill is applied also varies depending on the nature of the underground cavities and the height of the support needed. For example, in some of the massive sulfide mines in Ontario, backfill may have to support a mine roof hundreds of feet above the floor as described by YU and COUNTER (1983). At the Kidd Creek Mine, however, crushed wasterock is used as backfill because of the strength it offers when cemented and because the mine is located some distance from the mill which would require hauling tailings back to the mine. PATCHET (1977) reviewed testwork which indicated that cemented tailing slimes could successfully be used for deep underground backfill on Witwatersrand mines, and further development work in this area is currently being undertaken on the Witwatersrand.

At the Black Mountain Mineral Development operation which mines and mills a Cu-Pb-Zn ore in the arid norther Cape Province of South Africa, cemented tailings backfill is applied. It is interesting that at this site where water costs $1.20/m^3 (about R4.80/$2.40 per 1,000 U.S. gallons), fresh water is used in the backfill plant. This is because it is believed that if reclaimed tailings water were to be used, the strength of the cement could be adversely affected by organics in the water.

When ore is mined, it is not always possible to avoid getting cemented backfill into the muck, and sometimes a small quantity of cemented fill may reach the mill mixed in ore. Possibly because of dispersants used in the cement or because of other species introduced with the cement, flotation results appear to be impacted as a result. No quantitative data were available to confirm this.

Backfilled tailings bonded with cement usually result in minewater from those sections of the plant having a high pH, and metals in seepage from backfilled parts of the mine are usually at low concentrations.

In gold mills, i.e., those using CIP, it appears that a little cement addition to mill feed will not be detrimental to the process. For example, ANDERSON (1984) mentioned that at Battle Mountain operations of Duval Corp., a small amount of Type V portland cement is deliberately added to improve metallurgical performance in the presence of some cyanide-soluble copper.

In South Africa, the Chamber of Mines Research Laboratories had conceived the idea of an underground milling and flotation process which would preconcentrate mineral values underground which would be pumped to the surface, while tailings would be backfilled. Backfill can accommodate only 60% of the rock removed from the same cavity because of the 40% expansion factor when ore is milled.

One major drawback to backfilling is that today's tailings may well become tomorow's ore, just as today, tailings from past milling operations are also profitably milled, sometimes for the second or third times. If tailings are disposed of underground, these will not be available as an above ground resource for future recovery. On the other hand, tailings that have been backfilled underground with cement are unlikely to generate acid mine drainage.

Several massive sulfide ores contain large percentages of pyrrhotite, marcasite, and pyrite. If disposed of in conventional tailings impoundments, these become particularly bad acid generators. It would be logical to dispose of the high sulfide fraction underground in backfill. However, these materials can catch fire and are prone to spontaneous combustion underground which, of course, would be highly undesirable. Consequently, high sulfide material is not used as backfill.

At the Wedge Mine in New Brunswick from which ore was milled elsewhere, the mine cavity was backfilled with wasterock, and the site was very successfully restored thereafter. This solved some serious previous acid mine drainage problems.

Generally, in the U.S.A., minewater can be discharged under an NPDES permit, whereas mill and tailings decant solutions cannot except in exceptional circumstances in the U.S.A. It is interesting that since mill tailings have been used as underground backfill at Homestake Mining Company's Lead, South Dakota, operation, cyanide values started to appear in the minewater.

Many operations carry out a sand-slime split using cyclones. The sand is used for cemented backfill whereas the slimes are disposed of in above ground impoundments. Nonetheless, PATCHET (1977) showed that slimes could also be used satisfactorily as long as the moisture content can be controlled.

Emperor Gold Mines in Fiji deslime their tailings prior to backfilling. The cyclone overflow contains slimes which are disposed of in the slimes dam on the surface. The cyclone underflow is further washed in a rake classifier which produces an essentially slime-free sand which makes a very stable backfill material.

Denver Equipment Company has developed a centrifugal dewatering device which has been demonstrated at several mines for emplacement of tailings underground. Presumably, the

'tailspinner' also reclaims some water, but details would have to be obtained from the manufacturer:

DENVER EQUIPMENT DIVISION
Joy Manufacturing Company
5500 South Syracuse
Woodside 1, #105
Englewood, CO 80111
Michael Jensen
(303) 779-5586

Meanwhile, in South Africa, cement additives and improved pumping devices are also being evaluated so that the slimes tailings can be pumped with the lowest possible water content to the stopes for fast curing to be strong enough for roof support.

In this respect, it is known that lignin sulfonate can be used to keep cement fluid at lower moisture contents, but some caution is required if it is to be used where the cement, the additive, or water that has been in contact with the additive can get anywhere near a flotation circuit as lignin sulfonate is a dispersant that interfers with froth flotation.

Backfill Experiment: President Steyn Gold Mining Company:

Flotation tailings are neutralized and then submitted to the following procedure, all performed underground:

1) Addition of 120g nonionic flocculant (Allied Colloids Magnafloc 351 (PAM) is one that has been used).

2) The slurry is dewatered to 80% solids on a belt press supplied by:

MACHINERFABRIK ANDRITZ AG
Postfach 24
A 8045 Gracz-Andritz
Austria

3) Viscosity of the filterpress cake is reduced by adding tripolyphosphate. A small amount of cement is mixed in.

4) The viscosity modified high pulp density slurry is pumped via a Schwinn pump (positive displacement piston) which can pump the slurry 100-150m before it hardens up.

5) At the discharge end, a little Ca^{2+} is added as lime to destabilize the viscosity modifier by precipitating $Ca_3(PO_4)_2$.

6) Activated bentonite is added to the water recovered by the belt press to "kill" the excess flocculant. The water then goes to a thickener where the clay solids are recovered.

With 40 Stopes applying backfill at 10 tph for 8 hours per day, a total of 3,200 tpd solids would be disposed of. Water would be recovered, and the need for timber supports avoided. 27l/s water recovered would be lost in the 500 l/s machine water supply required in such a typical operation.

ABOVE GROUND TAILINGS PONDS WITH CONTROLLED RELEASE OF LIQUID

The controlled release of liquid from above ground tailings has been used for many years. Operations such as Rössing Uranium in Namibia lose water from their tailings pond through seepage. This seepage is collected in trenches and recycled to the plant. After being in contact with the metamorphosed carbonate substrata, the seepage solution improves markedly in quality. Its pH is raised, TDS dropped, and radionuclide levels and iron are dramatically lowered. This type of tailings pond, however, does not allow quite the degree of control of solutions lost as would be desired in many cases. Even at Rössing in 1984, a hydrological study was underway to determine where some of the seepage was escaping to. At mines such as Noranda's Mattabi and Brenda, tailings ponds seepage is collected by a trench and pumped back to the pond.

More controlled liquids release is achieved through the use of underdrains at the foot of the dam through which solutions can escape and be collected. This keeps the phreatic level on the inner surface of the tailings pond wall down. Examples where this system is used include AMAX, Inc. at their Climax mill tailings where AMAX claims the system was invented; at Rustenburg Platinum Mines, Transvaal; and at ERGO, Transvaal, amongst many others.

There are numerous configurations of surface tailings impoundments including those that use cyclones to separate sand and slime. When the spigotted sand fraction is used to build the wall of the impoundment and the slimes flow toward the interior of the impoundment, the wall will invariably be somewhat porous.

In some designs, tailings are discharged "downstream," allowing solids to settle at the inlet end and relying on the impoundment wall to contain the decanted solution. In others, tailings are released "upstream" from the dam wall, thereby forming an advancing beach which extends from the impoundment wall. ROBERTSON and VAN ZYL (1980); ROBERTSON, SHEPHERD, and VAN ZYL (1980); ROBERTSON, BAMBERG, and LANGE (1978), and VAN ZYL and ROBERTSON (1980) discuss these features of site selection and design of uranium tailings impoundments.

Subsurface drainage of tailings impoundments improves their stability, reduces hydraulic head on liners, improves water return to mill, and keeps the tailings better stabilized. VAN ZYL and ROBERTSON (1980) discuss the design, construction, and tailings management considerations involved. Poor control during construction of drains and during first filling with tailings can lead to the loss of dewatering capacity and even complete clogging of drains by the tailings themselves. Some practical consideration are discussed such as the influence of bottom surface slope of tailings impoundments, depositional procedures to minimize drain clogging, and installation of subsequent drains at higher levels in the tailings impoundment. The use of geotextile fabrics in the construction of underdrain collection sites and in the stabilization of impoundment structures is becoming routine. Other techniques include chimney drain configurations. Geotextile underdrains are installed, for example, in the huge new $30 million tailings impoundment constructed to contain East Daggafontein and

ERGO tailings east of Johannesburg. Older techniques involved the recovery of solution from the top of the pond through adjustable height penstocks connected to pipes that drain through the impoundment wall. A problem was presented when a very tall penstock connected to drains beneath the impoundment at INCO's Copper Cliff tailings pond was broken off at the base by a shift in the surface ice on the tailings pond. The total solution inventory was released to the Copper Cliff Creek with some damage. The question was how to replace the broken penstock. In the end, by far the most economical and practical way was to plug the original hole and to install a huge siphon over the dam wall. This has worked extremely well and offers a degree of safety not possible with very tall vertical penstocks in such a large deep impoundment. More details of the 3,200 foot long syphon arrangement are provided in the trip report on INCO, Copper Cliff, in Appendix I and can also be requested from:

Supervisor, Environmental Control

As environmental requirements (i.e., regulations governing discharge of effluents) have forced much greater recycle of tailings solutions and greater care in preventing seepage losses, so the TDS levels including species such as gypsum can build up in the pond until a point is reached where severe scaling may occur in the underdrains. This can result in clogging of underdrains and, although to date few cases have been ide[illegible] where this has actually occurred, the possibility has become an item of increasing concern to some operators who rely on underdrains to remove solution from their impoundment to keep the structure stable.

As mentioned above, one other way of "controlled" release of liquids is through construction of a porous impoundment which allows seepage through seepage which can then be collected by trenches or a wellfield installed around the perimeter of the impoundment as at Rössing and some of the southwestern U.S.A. copper recovery operations.

At Rössing, seepage collected in this way reduces the contaminant load in recycled water. The same applies at Quivira Mining Company in New Mexico where seepage reacts with the lime-rich aluvia and is partially neutralized by the material with which it come in contact.

ABOVE GROUND TAILINGS WITH IMPERMEABLE LINING

Increasingly, permits now call for lined tailings impoundments, particularly where geotechnical surveys do not indicate the [illegible]ce of virtually impermeable base material

or of conditions that will geochemically attenuate the migration of contaminants contained in seepage from an unlined impoundment.

California, for example, is a state that has insisted on double plastic membrane linings for impoundments unless very firm evidence is brought to bear that this is unnecessary, as has been the case for Homestake Mining Company;s new McLaughlin project where tailings are being disposed of over a natural clay base with 10^{-7} cm/s permeability.

Examples include Getty Mercur Mine at Toelle, Utah, where a bentonite stabilized sand has been used very effectively. More information on this innovative lining system may be available from:

GETTY MINING COMPANY
5250 South, 300 West, Suite 300
Salt Lake City, UT 84107
(801) 263-3850
Frank D. Wicks

Dawn Mining in Washington state is located in a climatic region with net precipitation. Formerly, this uranium mill discharged acidic tailings to an unlined pond which had a convenient leak allowing a bleed of undesirable species from tailings pond solution as well as a convenient loss of liquid to balance the incoming net precipitation.

However, once forced to line the pond (HDPE from Gundle Plastics was used), their operation was affected in several ways. Firstly, to keep the liquid level from rising too rapidly in the now leakproof pond, more tailings solution had to be recycled back to the mill in the place of fresh water that had previously been used. Secondly, without the salt bleed and with less dilution by fresh water, dissolved salt levels started to build up in the mill solutions. These then resulted in increased silica fouling of ion exchange resin and in a deterioration in ion exchange uranium recovery also due to higher levels of competing ions. In the end, the operation became uneconomic with falling uranium prices, and it has been shut down. In this case, excess high TDS mill solution cannot be disposed of by evaporation (as at Quivira Mining Company) because of the net precipitation climate, nor can excess salts be bled through seepage (as at Rössing Uranium) because of the impermeable tailings lining. In such a case, the only alternative appears to be the expensive route of desalination and the seeded slurry R.O. process which would appear to be particularly well suited. Alternatively, deep well injection of raffinates might be looked into.

WULFF, et al. (1980) described the new uranium mill tailings impoundment for Cotter Corporation in Canon City, Colorado. This operation recycles no tailings solutions so these have to be disposed of by evaporation from the tailings pond. Since the solid and liquid wastes from this mill were deemed to be toxic, a most important concern in the design of the new tailings disposal facility was containment, i.e., seepage control to prevent the degradation of downgradient waters. This was particularly critical at the

Cotter site which is only 2-3 miles upgradient from Canon City and the Arkansas River. The older millsite and existing mill tailings in the old permeable impoundment (not designed to be impermeable) have resulted in groundwater contamination problems, and the new tailings pond is to accommodate material moved from the old site in the reclamation thereof and the the old mill area. The materials underlying the new tailings site tested to have very high permeability rates on the eastern flanks. It was decided to line the entire pond with a membrane. The selected design was an above grade disposal system consisting of zoned earth embankments, a sophisticated lining system for the impoundment area, subdrains below the liner, and tailings dewatering drains above the liner as illustrated in the idealized section in their figure II-3 inserted below.

The foundations for the embankments and lined impoundment areas are excavated to or into bedrock. The embankments have an upstream sloping clay core backed by a continuous sloping drain and a horizontal drain in the valley area. The portion of the embankment downstream from the sloping drain consists primarily of random fill. The lining system consists of three layers: a compacted 0.46m (18 inch) clay subliner; a Hypalon membrane liner; and an 0.30m (12 inch) soil cover. The clay subliner is provided as a cushion for the Hypalon to prevent rock perforating the membrane and to act as a secondary liner in case the membrane is inadvertently perforated. The Hypalon thickness varies from 0.91 mm (36 mils) for the shallower areas, to 1.14mm (45 mils) for mid-depths, to 1.52mm (60 mils) for the greater depths. The membrane liner has a reinforcing fabric scrim. The 0.30m (12 inch) soil cover was provided to protect the Hypalon until it is covered by tailings.

The underdrain system consists of trenches excavated into bedrock, PVC pipe, and gravel backfill. The purpose of the underdrains is to collect seepage emanating from areas of the bedrock and transport the collected seepage beyond the toe of the dam so that there is not a buildup of hydrostatic pressures that could displace the liner.

To further reduce concerns about seepage over the very long term (i.e., after reclamation), the regulatory agencies requested that there be included a system to dewater the tailings to the greatest extent practical after the pond is decommissioned. Dewatering the tailings reduces the importance of the lining system in long-term containment of the waste. The dewatering system selected consists of a network of finger drains installed on top of the linings as shown in WULFF, et al.'s figures II-4 and II-5. the dewatering system is to function only during reclamation and after the free water in the ponds has evaporated.

The pH is adjusted in the mill from 1.7 to 4.2. Raising the pH has the following benefits:

1) Reduces the concentration of contaminants in the liquid hence decreasing the potential for contamination by seepage.

2) Reduces the potential for precipitates clogging the dewatering drains.

3) Reduces precipitates covering surface of tailings after evaporation, and reduces problems of placing reclamation cover. Costs for raising the pH were not included in their study.

Cotter Tailings System Quantities and Costs

The disposal system was designed to be constructed in stages. The ultimate height of the dam will be 35m (115 feet) with a crest length of about 1,524m (5,000 feet) and a tailings storage capacity of about 9,250,000 m^3 (7,500 acre-feet). The first stage embankment is 31m (101 feet) high, has a crest length of 1,497m (4,910 feet).

The total tailings solids storage capacity of the first stage impoundments is 3 million m^3 (2,400 acre feet). The first stage tailings storage will provide for approximately 3.4 million tonnes (3.8 million tons) of ore. Construction of the first stage tailings disposal facilities commenced in the summer of 1978 and was completed in 1979. Transfer of liquids from the old tailings impoundments began in the fall of 1979, and the new mill started operating in September, 1979, with the disposal of tailings in the new main impoundment at that time.

Mountain States Engineers were the designers and constructors for the mill Wahler Associates designed the tailings disposal facilities, and Stafford Construction Co. served as the construction subcontractor for the earthwork.

All earthwork materials for the embankments and liners were derived from the reservoir area and an area downstream of the dam except for sands and gravels for the various drains. Sand and gravels came from a commercial plant located near Canon City.

The first stage main and secondary embankments consisted of about 2.2 million m^3 (2.9 million cubic yards) of fill. Including clearing, grubbing, stripping, foundation preparation, embankment materials procurement and placement, and elimination of two old tailings ponds, the first stage embankments costs were about $13,000,000, which is an average of $5.86 per m^3 ($4.48 per cubic yard) of fill.

There were about 3,960m (13,000 lineal feet) of subdrains installed at a total cost of $190,000, or $47.97 per m ($14.62 per foot) of subdrain.

There were 623,000 m^2 (154 acres) of lining installed for a total cost of $5,300,000, including subliner, membrane liner, and cover. This is a cost of $8.50 per m^2 ($0.79 per square-foot of liner.

The tailings dewatering drains consisted of 8,930m (29,300 lineal feet) of drains and two sumps for installation of pumps. The total cost of the first stage tailings dewatering system was $303,000, for an average cost of $33.93 per m ($10.34 per lineal foot) of drain.

Construction of the remaining stages will provide 6.3 million m^3 (5,100 acre-feet) of additional storage. Data for storage provided by second stage construction and total storage are presented in Table II-1.

TABLE II-1

Future Stages and Total Tailings Storage Capacities

Future Stages		Total	
m^3	Metric Tons of Ore	m^3	Metric Tons of Ore
6.3 Million (5,100 Ac.Ft.)	7.3 Million (8 Million s. tons)	9.3 Million (7,500 Ac.Ft.)	10.7 Million (11.8 Million s. tons)

BELOW GRADE IMPOUNDMENT

Below grade impoundments have been considered in several cases for disposal of uranium mill tailings. To date, no example of the use of this method has been identified. WULFF, et al. (1980) evaluated four below grade disposal alternatives along with six other tailings disposal possibilities for Gulf Minerals' Mount Taylor uranium project in New Mexico. Below grade disposal involves excavating pits or trenches as shown in their figures III-1 and III-2.

advantages of trench disposal of tailings is that the tailings site can be reclaimed as trenches are filled rather than waiting until the very end as for large above grade disposal impoundments.

Below grade trench disposal was also considered for the pioneer Uravan operation proposed in Colorado which, like the Mount Taylor project never went ahead to production, for Homestake Mining Company's Pitch project in Colorado, and United Nuclear Corporation's Morton Ranch project in Wyoming.

Below grade disposal of tailings is generally the most expensive approach. This way may have particular appeal when ore is to be mined in a series of open pits which provide adequate room to accommodate at least 60% of the tailings below grade. To dispose of the balance, either additional pits must be excavated or above ground disposal in addition to the mine pits is necessary. Dry tailings, i.e., belt or rotary filter cake, have a lower

SUMMARY COMPARISON OF SIGNIFICANT PROJECT FACTORS

PROJECT CHARACTERISTIC	PROJECT: COTTER	PROJECT: MT. TAYLOR	PROJECT: HANSEN
Location	Located at existing mill 3 to 5 km (2 to 3 miles) from nearest populated area (Canon City, Colorado). Approximate elevation 1680 m (5,500 feet).	Remotely located approximately 10 km (6 miles) from mill site, 16 km (10 miles) from San Mateo, 50 km (30 miles) from Grants and 100 km (60 miles) from Albuquerque, New Mexico. Approximate elevation 2160 m (7,100 feet).	Remotely located approximately 1.6 km (1 mile) from mill site, and 30 km (20 miles from Canon City, Colorado. Approximate elevation 2470 m (8,100 feet).
Mill Rated Capacity	1360 tonnes/day (1500 tons/day)	3810 tonnes/day (4200 tons/day)	4080 tonnes/day (4500 tons/day)
Tailings Impoundment Capacity	9,250,000 m^3 (7,500 acre-feet) (20 years of operation)	11,220,000 m^3 (9.100 acre-feet) (20 years of operation; 50 percent of tailings, as sands, to underground mine backfill).	13,300,000 m^3 (10,800 acre-feet) (15 years of operation)
Site Geology	Located in middle of bowl formed by Chandler Syncline. Site underlain by 240 m (800-feet) thick Poison Canyon Formation (primarily sandstone interbedded with shales and conglomerates.) Site underlain at depth of about 300 m (1000 feet) by mined out coal seam. Shallow alluvial soil cover.	Located in Colorado Plateau geologic province on the San Mateo Dome. Rock units are complex sequence of folded and tilted sedimentary formations. Bedrock units beneath site and generally flat-lying sandstone, siltstone, and shale. Thick, collapsible alluvial soil cover in some locations.	Located in Thirty-Nine Mile Volcanic Field, with rock units of Precambrian, Paleozoic, Tertiary and Quaternary ages. Site overlies thick Echo Park sedimentary formation, which is principally friable to poorly indurated claystone with lenses of silty sandstone and clean sand. Echo Park slump blocks rim the site valley. Stability of these is one primary consideration.
Groundwater Conditions	Seepage from old unlined tailings pond was causing concern for groundwater degradation. New facility will provide for reclamation of leaking ponds. Deep water table exists in old mine workings. Groundwater monitoring program in progress and for foreseeable future to verify expected quality improvement.	Near-surface geologic units are unsaturated to depths of several hundred feet. Major groundwater model study was conducted to predict performance.	Artesian conditions exist in deep aquifer, producing hydrostatic pressures to near natural ground level at some locations. Minor groundwater in shallow alluvium along streambeds.
Approximate Drainage Area Above Disposal Site	2.3 km^2 (0.9 Square Miles)	10.1 km^2 (3.9 Square Miles) (total above evaporation pond)	3.1 km^2 (1.2 Square Miles)
Method of Waste Liquid Disposal	Evaporated from tailings pond	Evaporated from separate evaporation pond for all alternatives except Alternative 1.	Waste liquids recycled - no evaporation facilities required.
Method of Handling Natural Basin Runoff During Operation	Small Diversion ditch and catch basin above tailings pond. Impounded water pumped past tailings dam. Tailings impoundment still designed to retain PMF series.	Diversion facilities to route PMF past disposal facilities for all alternatives.	Various methods, depending on alternative. Single dam, head of valley impoundment would retain PMF series. Cell and total burial schemes would require major diversion facilities around disposal sites.
Maximum Height of Tailings Retention Embankment Above Natural Ground	35 m (115 feet)	Alt. 1 33 m (107 feet) Alt. 3 19 m (61 feet) Alt. 5 14 m (47 feet) Alt. 6 No retention embankment Alt. 8 19 m (61 feet) Alt. 9 No retention embankment Alt. 10 No retention embankment	Total Below Ground - No embankment Deep Excavation, Multicell Disposal - 24 m (78 feet) Shallow Excavation Multicell Disposal - 27 m (87 feet) Single Dam, Head of Valley Impoundment - 55 m (180 feet)
Tailings Impoundment Lining Provisions	0.5 m (18 inches) of compacted clay, overlain by 0.9 to 1.5 mm (36 to 60 mil) Hypalon, overlain by 0.30 m (12 inches) of soil cover throughout reservoir. Subdrain system beneath compacted clay.	Limited areas of impoundment require compacted clay liner in Alt. 1. Cell bottoms would be scarified and compacted in Alts. 3, 5 and 6. Cell sides and bottoms scarified and compacted in Alt. 8. No lining in Alts. 9 and 10.	Compacted clay liner proposed at selected locations to be determined during construction for all alternatives.

TAILINGS DISPOSAL CONCEPTUAL PLAN

FIGURE III-2

TYPICAL TRENCH BURIAL SECTION

volume than when disposed of as a pulp and would be considered in conjunction with below grade disposal.

When using below grade disposal, one of the problems is how to line the sides of the pits which are conceptually steep.

WULFF, et al. (1980) showed that the cost of blow grade tailings disposal at Mount Taylor for the first stage ranged between $5.46-$45.55 per metric ton of ore. This alternative was considerably more expensive than the other alternatives evaluated.

COMBINATION BELOW AND ABOVE GRADE DISPOSAL

Above and below grade disposal of tailings may be an attractive alternative when ore is mined in a series of open pits and where the tailings provide a convenient way of filling the pits to reclaim the area.

In Colorado Springs, a sand and gravel quarrying company evaluated the possibility of retreating a 10 million ton pile of gold mill tailings with a view to disposing of tailings from the retreatment process in their sand and gravel pits. WULF, et al. (1980)'s evaluation found that even this alternative worked out marginally more expensive than in a single dam impounding tailings in the head of a valley.

ROBINSKY THICKENED TAILINGS METHOD

The Robinsky thickened tialings method uses a thickener to dewater tailings before they are discharged to a the central point of a large single impoundment area. As tailings are discharged, they are intended to spread out into thin layers from which solution decants and runs downgradient to retaining water impoundments on the outer perimeter of the tailings area. Six advantages are claimed:

1) The cone-shaped tailings pile can support a greater angle of repose than unthickened tailings. Consequently, the same size impoundment area can accommodate a greater volume of tailings.

2) Since solution decants to a pool along the outer perimeter of the area, there is a larger evaporation area and being shallower, the height and size of the impoundment wall can be a simpler structure.

3) Since solution is reclaimed from the tailings in a thickener, it can be returned to the mill without spending time in the tailings area. This is useful if recyclable reagents,

Figure 1 Comparison of the conventional and thickened tailing disposal systems

Figure 2 Typical laboratory tailing deposition test results

Figure 3 Laboratory test results showing tailing deposition curves. Tailing samples were obtained from different mines

Source: ROBINSKY (1981)

e.g., cyanide in a CIP tailings, are contained in solution which would be lost in a large open pond.

4) Because the tailings area covers a smaller area than conventional tailings in areas with net precipitation, less runoff and precipitation will be collected.

5) The Robinsky thickened disposal site is quicker to construct than most conventional tailings impoundments.

6) The possibility of scale clogging underdrains does not arise.

Critics of the Robinsky tailings method point out that many ores would yield a tailings that would not be stable to earthquakes. More information is described by ROBINSKY (1981) or can be requested from:

E. I. ROBINSKY
E. I. Robinsky Associates Ltd.
66 Lytton Blvd.
Toronto, Ontario
Canada M4R 1L3

One disadvantage of the Robinsky thickened tailings method at Kidd Creek Mines Ltd., Timmins, appears to be the problem of dusting during dry months when the wind blows. By building conventional tailings impoundments in sections, one at a time, each one, when full, can be vegetated as the next one is operational.

"DRY" TAILINGS DISPOSAL

"Dry" tailings disposal refers to the emplacement of dewatered tailings by conveyor belt, or dewatering them at the tailings site using a filter or belt press to recover water and reagent values for recycle.

The Nuclear Regulatory Commission insisted that uranium mills for which permits were applied in the U.S.A. evaluate this alternative. In this respect, belt filtration was considered to offer major advantages at one point. If the filters are to be installed with a view to washing the leached pulp as well as dewatering of tailings, then probably belt filters or the more expensive rotary filter should be considered. If, however, the filter is primarily there to make dry tailings and to recover solution (possibly with reagent and/or incremental resource values), then a disc filter would probably be more appropriate because they cost less. For the lowest possible cake moisture, belt presses could be considered. There are several on the market including those offered by EIMCO (Salt Lake City), DRAVO CORP. (Pittsburgh), PARKSON (Fort Lauderdale), and ARUS-ANDRITZ CORP.

The United Nuclear Corporation evaluated dry tailings disposal for the Morton Ranch Project in Wyoming and rejected it for two reasons: Conveyor transport of dry tailings in winter would require convered and heated conveyors; and secondly, during the hot, dry, and windy Wyoming summers, there would be a real possibility of windblown losses. The cost of covered conveyors would be exorbitant.

Two dry tailings operations were identified, both disposing of uranium tailings, and it is known that a western U.S.A. silver recovery operation is considering dry tailings. Motivation of the two uranium operations is to maximize water recycling and to minimize water pollution. The silver operator's motive is to recover as much cyanide value with the tailings solution as possible.

This 250 tpd mill also employed the latest Philippe belt filter to produce dry tailings for below ground disposal. The plant was visited just as the filters were being commissioned, and it was too early to determine how effective the dry tailings disposal was, i.e., what cake moisture is achieved, etc.

"SEMI-DRY" OR "SUB-AERIAL" TAILING DISPOSAL

The principle behind subaerial tailings disposal is to apply a tailings slurry in thin layers. Then the fluid is decanted off for recycle or evaporation, and the upper surface allowed to dry. When this occurs, it shrinks and cracks. The next layer of tailings then fills the cracks in the previous layer. It is also decanted and allowed to dry and crack, etc. Underdrains also remove any free moisture from below the impoundment.

"Semi-dry" tailings disposal are applied at numerous Witwatersrand gold-uranium tailings slimes disposal sites with excellent success. Of course, there is a warm, net evaporation climate and abundant, not yet too expensive labor to help make this sytem work.

Subaerial tailings disposal were first introduced in North America by Bruce Knight of Knight and Piesold in Vancouver.

A wellknown, successful application of subaerial tailings in Canada has been at:

KEY LAKE MINING CORPORATION
229 4th Avenue South
Saskatoon, Saskatchewan S7K 4K3
(306) 665-7000
Bernard Rosner
Engineering Manager
Joe Anderson
Environmental Manager

At Key Lake, a 12-inch layer of bentonite-stabilized sand (12 Kg bentonite per m^2) privides a satisfactory lower seal for the tailings pond. The bentonite-stabilized lining is covered with 3 feet of porous sand covering a system of perforated pipe to drain any fluids from the sloped lining. The tailings impoundment base slopes at 1/2-1° in two directions to drain fluids to a corner sump.

A very important aspect of the sub-aerial tailings technique practised at Key Lake is their disposal of precipitated arsenic and heavy metals sludges from the water treatment plant as well as precipitated $BaRaSO_4$. Because the precipitates are mixed with tailings and encapsulated, it is felt that they will be significantly more stable than when precipitates are mixed with tailings for disposal to a conventional tailings pond which allows diffusion of liquids throughout the submerged material. The Key Lake tailings, after subaerial deposition, are designed to be extremely impermeable and will not allow water containing CO_2 to reach the precipitate encapsulated in the mass of tailings. The importance of this lies in observations referred to in Chapter 29 that ferric arsenate precipitates may not be stable long term in the presence of CO_2 dissolved in water, just as the same observation has been made about $BaRaSO_4$. Therefore, the encapsulation of these and amphoteric base metal precipitates is likely to be very much safer than simply mixing them into conventional tailings. That is provided sub-aerial deposition works as well in their climate as laboratory simulation indicated.

BLIGHT and CALDWELL (1984) and WATES (1983) show how in South Africa the top surface of the subaerial deposited slimes are divided into paddocks for day and for night tailings addition. They also show that the retention of water on the top surface of a tailings as well as measures such as erosion protection by the covering of slopes with rock may lead to instability of the slopes under some circumstances.

The maximum practical rate of rise and hence the minimum cycle time required for effective desication, stable phreatic surface conditions, and access requirements is commonly thought to be a unique value for a given climatic region. For gold and uranium tailings impoundments in the Transvaal and Orange Free State, WATES (1983) points out that a value of 2.5m per year has been adopted as a maximum rate of rise. He points out, however, that it is not unique and that cycle time, which depends on the relative density of the tailings (i.e., water content), should be limited. He pointed out that about 1 ton of water goes to the dam for each ton of solids in a tailing with a specific gravity of 1.45, while about 3 tons of water goes with each ton of solids in a tailing with an SG of 1.18. Since the capital, maintenance, and running costs of pumps and piping are approximately proportional to the volume of slurry pumped, the cost of disposal per day can be significantly greater for slime of low solids content.

It is of interest that the tailings at the McLaughlin property of Homestake Mining Company will use a modified version of the subaerial tailings deposition technique.

Also of interest is the observation that Western Mines at their Myra Falls operation on Vancouver Island, British Columbia, is reputedly testing subaerial tailings deposition for tailings containing sulfides. Certainly, the problem of acid mine drainage generation from tailings containing sulfide minerals has yet to be resolved. The question is whether "sub-aerial" or "semi-dry" tailings disposal of this type of material could be adapted to provide adequate encapsulation of the sulfides in a low porosity material to limit the

migration of water into the tailings once lain down, or to limit migration out of acid. It will be most interesting to learn more about the experiments carried out by Western Mining on sulfide-bearing tailings and "semi-dry" tailings disposal techniques, because this operation is located in a net precipitation climate which will likely require some adaptation of the technique.

The Key Lake Mining tailings disposal method was designed with the help of Bruce Knight whose address is shown above and tested at:

SHERRITT-GORDON MINES LTD.
Fort Saskatchewan, Alberta
Canada T8L 2P2
(403) 898-6911
Herbert Veltman

Similar tests in which seasons over several years were simulated for Midwest Lake uranium ore (ESSO) were carried out in Mississauga by:

ONTARIO RESEARCH FOUNDATION
Dept. of Metallurgy
Sheridan Park Research Community
Mississauga, Ontario
Canada L5K 1B3
(416) 822-4111
V. Lakshmanan

The interesting aspect is that sub-aerial tailings disposal works also in parts of the world with very cold climates.

Certainly, in Witwatersrand slimes dams, the generation of acid from pyrite in the tailings seem to be inhibited relative to older sand tailings despite the fact that the more finely divided pyrite should oxidize faster--according to SMITH, et al. (1984). The question remains to what extent this inhibition can be enhanced were this feature important, possibly through an additive or some other approach.

The strong South African influence in "sub-aerial" expertise is due to the fact that this technique was developed there and is still quite new in North America where it is relatively experimental due to the different climatic conditions and objectives for its use.

SUBMARINE TAILINGS DISPOSAL

According to HAWLEY (1975), submarine disposal of tailings is practised by Bougainville Copper on Bougainville Island in the South Pacific (78,000 tpd); Utah Mines Ltd. operations at Rupert Inlet, Vancouver Island; and at Atlas Consolidated Mining, Toledo City, Cebu, Philippines (64,000 tpd) and also by the nickel recovery operations on New Caledonia. AMAX also deposits tailings from a molybdenum recovery operation in British Columbia into the sea, and one of the very largest of all submarine tailings disposal cases is planned by U.S. Borax and Chemical Company for their Quartz Hill molybdenum mine in southeastern Alaska.

The advantage of submarine tailings disposal is that there is no tailings site that requires maintenance or post-operation closure. Also, there is no acid mine drainage generated that can be treated for discharge. To date, information available on the effects on the marine environment of submarine tailings is not comprehensive. It is believed that Professor D. V. Ellis, editor of a book on the subject of marine tailings disposal, may have additional observations:

PROFESSOR D. V. ELLIS
Dept. of Biology
University of Victoria
Post Office Box 1700
Victoria, B.C.

(604) 477-6911
Telex: 049-7222

The economic advantages of submarine tailings disposal are great enough that it would be economically attractive to pump tailings over a considerable distance to be able to discharge them to the ocean.

The environmental impact of submarine tailings disposal is said to be minimal, but where is the study data to prove this. Jacques Cousteau investigated a submarine tailings disposal site off New Caledonia and reported very serious submarine environment damage.

Justification of submarine tailings discharge might be possible on environmental grounds through a study of the submarine environmental impact of doing so at existing sites. No such thorough study has been encountered. One of the problems is the lack of baseline data for such sites before the tailings were discharged.

Disadvantages of submarine tailings disposal include the loss of the opportunity to reclaim water or perhaps reagent values in tailings decant solution. On the other hand, if fresh water is available, this gives the operators grounds to use it throughout the plant which can have process benefits. Alternatively, tailings could be thickened prior to ocean dumping, allowing at least some water to be reclaimed.

DEEP LAKE DISPOSAL OF TAILINGS

Deep Lake disposal of sulfide tailings offers several advantages especially where these contain sulfide minerals. Firstly, the tailings are out of site and may never present a reclamation or AMD problem.

Not too many parts of the world have deep lakes--of those that do, the best known is Canada.

It is understood that, to date, licensing authorities have been against the issuance of permits for deep lake disposal of tailings. The reasons are not clear.

It is also understood that Hudson Bay Mining and Smelting used to dispose of tailings into a deep lake and that the environmental effects of doing so were found to be negligible. Details of the lake and identification of the operation that disposed of tailings in this way were not obtained. The study of environmental aspects was also not found--the hearsay comment is passed on for what it is worth in case the details can be tracked down through Hudson Bay Mining and Smelting.

At Westmin Resources' Myra Falls operation near Campbell River, B.C., on Vancouver Island, flotation tailings after alkaline chlorination for cyanide destruction were disposed of into the deep Buttle Lake from which the nearby townships draw their drinking water. It is reputed that this operation now employs subaerial deposition on an above ground

tailings pond which implies that they no longer dispose of tailings into the lake. No details were obtained on the subaerial tailings disposal nor if or why deep lake disposal ceased. Sponsors may wish to get in touch with A. G. Eccles, Mill Superintendent at this operation to learn more about deep lake disposal as well as subaerial deposition. A copy of his description of deep lake tailings disposal and cyanide destruction is included in Chapter 40 on cyanide destruction.

TO LINE OR NOT TO LINE A TAILINGS POND

Impoundment linings, whether clay or synthetic membranes (single or double), are very expensive. In some cases, lining a tailings pond upsets the water and salt balance as well, resulting in metallurgical recovery complications.

Whether or not to line a tailings impoundment depends on the answer to five questions:

1. What is the nature of the contaminants that will seep from the pond if unlined. That means what species in the tailings solution and what species will be generated as the tailings age, e.g., acid, base metals, reagents.

2. What is the nature of the material below the tailings impoundment. What is the porosity of the material--are there fractures which will leak.

3. Will contaminants in seepage be geochemically attenuated by the chemistry of the material underlying the tailings. Will this be adequate to protect aquifers and surface water quality.

4. What is the quality of water in the underlying aquifer that will be impacted. Is it already of such poor quality as to render it unusable and therefore not worth protecting. Can this be documented in a way that regulatory agencies will approve further contamination of the aquifer?

5. What do the local regulations require. Possibly, lining the pond is a prerequisite for a permit and, if so, what type of linings do they specify.

GEOCHEMICAL ATTENUATION OF SEEPAGE CONTAMINANTS

From a technical standpoint, geochemical attenuation of tailings seepage can be very powerful and a useful aid in tailings impoundment. In fact, this may be a most valuable criteria in selecting one of several alternative impoundment sites. Seepage from some tailings ponds is a desirable feature. One such example would be a tailings pond located at a site with net precipitation where a closed system recycle would interfere with

DOWNSTREAM DISCHARGE TAILINGS POND IN NEVADA

metallurgical efficiency (e.g., uranium recovery by ion exchange) located over a highly saline aquifer where the sediments over which the tailings are impounded have a chemistry that will neutralize the acid in the seepage and attenuate the contaminant migration geochemically.

GROUND WATER AND CONTAMINANT MIGRATION: PRINCIPLES, MONITORING, REGULATIONS, AND CONTROL MEASURES

Jim V. Rouse

May, 1984

INTRODUCTION

The state of awareness of the vulnerability of ground water to pollution, and the concern over such ground-water pollution occurrence and migration has come a long way since the days when a court ruled that the movement of ground water was such a mysterious and mystical process that it could not be known to mankind. Almost every present day technical publication deals with the real or supposed potential for ground-water contamination. EPA and the various state regulatory agencies are devoting significant amounts of time and effort to assuring that such migration does not occur.

Far from being a mysterious and mystical process which cannot be understood by mankind, the movement of ground water and dissolved contaminants obeys a series of rather straight-forward laws, and can easily be understood by a common sense approach.

The idea of "underground rivers" is totally out of place in virtually all situations of ground-water contamination. Available information shows that there are natural geochemical attenuation mechanisms at work to retard or prevent the spread of contaminants throughout the water mass. While it is not appropriate to depend solely on such natural attenuation, it does form a vital secondary line of defense beyond the engineered controls which man can emplace. It is appropriate to start

spreading this good news to regulatory agencies, that ground water does have certain natural geochemical purification processes.

GROUND-WATER HYDROLOGY PRINCIPLES

Far from being a separate, mystical and mysterious fluid, ground water is only one type of water which is interrelated to surface water and atmospheric water by means of the hydrologic cycle. This was very well summarized by King Solomon in the book of Ecclesiastes, when he stated that "all the rivers run into the sea but the sea is not full". Ground water includes only that portion of the overall hydrologic cycle where movement is through natural geologic media under saturated flow conditions. Ground-water recharge occurs when precipitation, in the form of rain or snow, infiltrates the soil and the unsaturated (or "vadose") zone to reach the ground water mass below the "water table". Additional recharge occurs from the infiltration of water from surface water courses, either permanent or temporary stream flow. All of this is schematically illustrated on Figure 1.

Ground-water movement occurs from areas of high potential energy to areas of lower potential energy. Thus, ground water moves "downhill", but the problem is defining what is "downhill". Flow generally occurs through a myriad of very small pore spaces between grains of mineral matter, and as such is extremely slow, with rates in the order of a few hundreths to a few tenths of a foot per day being quite common.

Figure 1 - The Hydrologic Cycle

From Groundwater And Wells, Johnson, 1975, p.16

J. H. KLEINFELDER & ASSOCIATES GEOTECHNICAL CONSULTANTS — MATERIALS TESTING	ENVIROLOGIC SERVICES INTERNATIONAL Denver, Colorado (303) 759-2611
PREPARED BY: WTD DATE: 7/11/84	
CHECKED BY: CJR DATE: 7/12/84	PROJECT NO. Figure 1

Ground water discharges into streams to support the base flow of the stream, and also discharges into the atmosphere by means of direct evaporation of water at seeps, or by transpiration of water from phreatophytes (water loving plants) whose roots penetrate to the water table. Ground-water discharge thus rejoins the above-ground portion of the hydrologic cycle as either surface water or atmospheric water. Ground-water discharge also plays a major role in man's activities, with approximately half of the total water consumption in the United States being supplied by wells.

There are several units of measurement associated with ground-water hydrology which are quite important. One of the most simplest of these is the piezometric surface elevation, or the water table elevation for those aquifers which are at atmospheric pressure on the upper surface. Artesian aquifers are those aquifers which are confined on the upper surface by an overlying, impermeable strata. The piezometric surface for a confined aquifer is an imaginary surface significantly above the upper surface of the aquifer, and would be marked by the elevation to which water would rise through an infinite number of artesian wells penetrating the confining layer. Artesian aquifers are not necessarily flowing aquifers, but rather only flow when the piezometric surface is at an elevation higher than the land surface.

The piezometric surface, or water table elevation, is commonly measured by means of an electric sounding tape lowered down a

well until contact is made. The depth of water from a known elevation point is measured and is then converted into piezometric surface elevation by subtraction of the depth of water from the elevation of the measuring point. Water table aquifers generally show seasonal fluctuations in elevation; artesian aquifers frequently display rather marked variations caused by the passage of weather systems, the passage of a train near the well, or in response to nearby pumpage.

The permeability of a rock unit is the ability of that unit to transmit water under saturated flow conditions. Permeability is frequently stated in terms of velocity units such as feet per day but can only be converted to ground-water velocities by multiplication of the permeability times the ground-water gradient.

The transmissivity of an aquifer is the permeability multiplied by the vertical thickness of the aquifer unit. It is directly calculated by means of aquifer tests in which a measured quantity or flow rate is pumped from a pumping well over a period of time, frequently 24 to 48 hours, and the rate of ground-water decline in the pumped and/or monitor wells in noted.

CONTAMINANT MIGRATION AND FIXATION

Contaminants which enter the ground-water mass may move at the same rate as the ground-water particle, (in which case they are referred to as "conservative" contaminants), or they may be

retarded relative to the rate of ground-water flow, or may actually be immobilized within the aquifer. Contaminants with this latter form of behavior are referred to as "non-conservative" constituents. Obviously, the general situation is somewhere between behavior as a conservative and totally non-conservative constituent. Certain contaminants of concern tend to be very close to totally conservative, such as hexavalent chromium, organic solvents, and major ions such as chloride and sodium. Materials which are severely retarded in the ground-water environment include radionuclides such as radium. Most of the common heavy metals are retarded in a finite order which has been developed by studies through numerous areas of ground-water pollution.

CONCEPTUAL GEOCHEMICAL MODEL

Based on numerous studies, it is possible to develop a conceptual geochemical removal mechanism model to address the behavior of those contaminants which are retarded by geochemical reactions. The attached Appendix A summarizes the various geochemical reactions, which may take place in the subsurface, and provides additional details on the removal affecting an acidic, contaminant plume which is in reaction with the natural aquifer material. The following information, based on the various reactions, summarizes a conceptual geochemical model for contaminant mobilization, transport, and removal. This model is similar to that presented by Cherry, Shepherd, and Morin (February 14-18, 1982) and is based on the results of many

investigators in this field, as well as the authors' own field experience.

When a highly acidic water percolates from a process water impoundment, the initiation of calcite dissolution occurs at the advancing wetted front. As the plume proceeds downgradient, a total of three zones form, illustrated on Figure 2 and described in the following section.

The first zone, which may be termed the "acid" or "core" zone, consists of ground water with a quality virtually identical to that of the pond water. The water is characterized by extremely low pH, the presence of very high sulfate ion concentrations, often in the form of ferrous sulfate complex, and other contaminants including numerous heavy and toxic metals. Radiochemical contaminants are strongly sorbed on aquifer clays and rarely move more than a few meters.

The acid or core zone described above is characterized by an area in which all calcite minerals present in the soil or rock column have been dissolved and reacted and the ground water is similar in quality to that of the source. In areas with soil rich in carbonate minerals, such reaction, and the resultant acid or core zone, is often a few meters in extent. By contrast, the second conceptual zone, termed the "neutralizing" zone, is the site of active calcite dissolution and the formation of chemical precipitates, including metal hydroxides, calcium phosphate, calcium flouride, and gypsum. This zone is further characterized

Figure 2 - Conceptual Model Of Geochemical Zones

ENVIROLOGIC SERVICES INTERNATIONAL

Denver, Colorado (303) 759-2611

A DIVISION OF J.H. KLEINFELDER

DATE: 7/12/84	Figure 2

by continuing high values of dissolved metals, in accordance with the order of metal hydroxide removal. The types of metals involved can be directly related to the resultant pH of the solution. The front and rear boundaries of this zone are not sharp lines, but rather tend to be zones which advance downgradient in response to chemical reactions. Radiochemical contaminants are generally absent, having been sorbed and coprecipitated in the acid zone.

Downgradient of the neutralizing zone is an area which can be termed the "neutralized" zone, characterized by high concentrations of total dissolved solids representing a saturated calcium sulfate solution. The area is further characterized by little in the way of calcite reaction, with virtually all of the calcite originally present in the soil or rock still remaining available for reaction. The upgradient boundary between the neutralizing and neutralized zones is gradational, depending on the metal hydroxide removal stage. The downgradient boundary of this zone is represented by increasing total dissolved solids concentrations.

GROUND WATER MONITORING

The design, installation, and operation of a ground-water monitoring system to adequately define the horizontal, vertical, and temporal variability of ground-water quality dictates a thorough knowledge of the ground-water flow system. Numerous extensive articles and manuals have been prepared on the proper design, construction, and operation of such a system, and should be consulted prior to the beginning of such activities. In addition, the appropriate state and Federal regulations for hazardous waste sites should also be considered, since they dictate facility location, construction, and operation, as well as the statistical analysis of the resultant data.

While any evaluation of the ground-water resource should utilize to the maximum extent practicable any existing well, all too frequently such wells are not located at suitable sites, are not completed in the appropriate horizon, or information does not exist on the construction techniques. In such cases, monitor wells must be drilled and completed specifically for the purpose of ground-water monitoring.

Monitor Well Construction

Extreme care must be taken during the construction of monitor wells to assure that the wells properly sample the aquifer of interest, and do not allow for the vertical migration of contamination from one zone to the other. Prior to monitor well construction, state agencies should be contacted for the latest requirements concerning permit and completion requirements.

General experience has shown that well clusters or "nests" are more suitable for routine monitoring in the vertical dimension than multiple-completion wells because of their simpler structure. However, each has its advantage under certain circumstances, as discussed in a following section.

Care should be exercised in selection of the material used in well construction, considering geochemical site conditions. PVC well casing is usually preferred over metal, unless samples are to be collected for organics. Sand or gravel for well packing should be checked for high concentrations of regional material. Johnson (1972) provides an excellent general discussion of wel' construction techniques.

The most common monitor well construction is one open over a vertical section of the aquifer, used to obtain ground-water samples from un-onsolidated sediments or semi-consolidated rocks. In consolidated rock, open bore holes without casing can serve the same purpose. Such a well is not effective in providing information on the vertical distribution of contaminants. Most existing wells converted to monitor well use are of the open section type. All too frequently, such open-section wells are completed to a depth just below the water table, which has the obvious major drawback that only the upper portion of the aquifer and the most recently infiltrated contaminant is sampled. In some cases, wells are screened over the entire aquifer thickness in an effort to counteract this shortcoming. This solution may mask contamination by excessive dilution, and provides no

information on the vertical distribution of the contamination due to the composite measure of the sample.

Piezometers are used to measure water pressure in aquifers and to obtain water samples from a specified depth. A piezometer is isolated from other pressure environments by an impermeable clay or cement seal. If the well screen is properly isolated by an impermeable seal placed immediately above the screen, a piezometer can also be used to measure vertical head differences under unconfined conditions. The important difference between a piezometer and a well screened over the entire vertical interval is the annular seal. Such a relatively impermeable seal will prevent downward movement of contaminant into uncontaminated zones of the aquifer.

Multiple piezometers with screen intervals set at different depths in a single location can be used to form a well cluster or "nest". Such a nest allows the definition of the piezometric elevation as a function of depth within the aquifer, and also allows the collection of water-quality samples from various depths. Contaminant plumes are often more dense than the receiving ground water, and sink to a lower confining layer with subsequent movement as a density current in the aquifer, with little mixing. Thus, a nest of piezometers or short-screen wells can define that portion of the aquifer which is contaminated, and allow for the development of remedial measures which limits the quantity of ground water which must be pumped and treated.

Aquifer Tests and Permeability Determination

By far the most common method of determining the permeability of an aquifer is by means of aquifer or pump tests. Water wells are generally tested for two reasons:

1) To obtain information about the performance and efficiency of the well, and
2) To provide information on the water-yielding characteristics of an aquifer or the interrelationships of different hydrologic units.

In the conduct of an aquifer test, it is assumed that a thorough pre-test site evaluation will be conducted by trained hydrogeologists. The details of such an evaluation are beyond the scope of this paper, but are discussed by Stallman (1971) and Fedora (1980). In general, this evaluation should include study of pertinent well logs and other data in order to determine and estimate as many of the characteristics of the aquifer as possible. Either of the previously mentioned test objectives will require collection of the following data:

1) Static water levels before pumping starts
2) Location of and distance between pumping and observation wells
3) Barometric pressure change during test
4) Pumping rate or rates of discharge from the pumped well
5) Dynamic water levels or pumping levels at various time intervals during the pumping period
6) Time of starting the pump

7) Time of any change in discharge rate and new pumping rate

8) Time of stopping the pump

9) Dynamic water levels after cessation of pumping

All equipment to be used during the tests should be checked thoroughly. If a test must be terminated prematurely because of mechanical failure, all of the previous efforts may be useless and require repeating. Prior to testing, the well should be thoroughly developed or its response to the test may not be meaningful. A pump of appropriate capacity should then be installed. Such a pump should be capable of continuously delivering one quarter to one half of the maximum well yield.

The pumping rate during testing should be kept as constant as possible, and should not vary more than 10% during the test. The best control is provided by a valve in the discharge line. The valve should be partially closed to restrict the initial discharge. Partially closing the valve tends to reduce any fluctuation in pump rate due to varying line voltage. As the water level falls during pumping, the lift increases and the discharge of the pump tends to decline. With the valve initially restricted, it can be opened as necessary during the test to maintain a constant rate.

Small pumping rates can be determined by observing the time necessary to fill a container of known volume, such as a 55 gallon drum or 5 gallon bucket. Commercial water meters may also

be installed in the discharge line. Subtracting two readings taken exactly one minute apart gives the pumping rate in gallons per minute. This apparatus has the disadvantage of delays in getting initial values at the start of a test when the rate is being adjusted. The water meter and volumetric methods for measuring discharge rate are most useful for flows of less than 100 gallons per minute.

Discharges from turbine or centrifugal pumps are often measured with a circular orifice plate. The discharge pipe must be straight and level for a distance of at least two meters back of the orifice plate (Johnson, 1972).

No matter what method of flow measurement is used, water discharged from the pumped well must be conducted away from the well head so that it cannot recharge the aquifer during the test. Depth of water in the pumped well must be measured several times during conduct of the test. Water level measurements should be recorded to the nearest 5 millimeters or 0.02 feet, depending on planned units of measurement. Measurements should be made at 30 second intervals during the first 5 minutes, 5 minute intervals for the first hour, and every 20 minutes for approximately 2 hours subsequently. Subsequent measurements can be made hourly for the first day of pumping and then at a lesser frequency. Measurements must be made from a fixed reference point such as the top of the casing to the water level. The actual elevation of the reference point should be determined to allow calculation of the water-table elevation.

Once the pumping test has been completed, water level recovery measurements should be made. This is simply the reverse process of the pumping time. After these data have been collected, appropriate data analysis should be made. Discussions of aquifer analysis are provided in numerous texts such as Freeze & Cherry (1979), Davis & DeWiest (1966), or Johnson (1972).

In situations where the cost of a full pump test is not warranted, and especially where low permeability sediments are encountered, "slug" or "bail" tests can be utilized. Both tests are initiated by causing an "instantaneous" change in the water level of the well by sudden addition (slug test) or removal (bail test) of a known volume of water. Recovery of the water level is then noted and recorded. An excellent discussion of the conduct of such tests is provided by Freeze & Cherry (1979).

Slug and bail tests yield results that are, technically, only indicative of the area immediately surrounding the bore hole. As such, there are some limitations that must be considered. Accurate results depend on the response of the bore hole. Poor response due to incomplete development or screen clogging may result in inaccurate calculated values. Also, if the well was developed by surging or backwashing prior to the test, values may simply reflect the increased conductivity in the gravel pack surrounding the bore. If the wells are to be used for water quality monitoring, care should be used in selection of the water added during a slug test to avoid false water quality data.

Vadose Zone Monitoring

In many cases, it is desirable to know the concentration of potential contaminants in the soil moisture above the groundwater, so as to allow initiation of remedial measures prior to the contamination of the saturated zone. Such monitoring of the unsaturated or vadose zone can best be accomplished by means of pressure/vacuum lysimeters. Pressure/vacuum lysimeters consist of a porous ceramic or Teflon cup capable of holding a vacuum, a small-diameter sample accumulation chamber of PVC pipe, and two sampling tubes leading to the surface. Once the sampler is emplaced, a vacuum is applied to the cup, causing soil moisture to move into the sampler. The sample is then recovered by releasing the vacuum and applying pressure to the delivery tube, forcing the accumulated water to the surface through the sampling tube. Figure 3 illustrates a typical lysimeter installation.

Lysimeters yield a limited quantity of sample, generally less than one liter, depending on such factors as soil type and moisture content, sampler construction, and depth of installation. For installations at great depth, a lysimeter must include a check valve to prevent forcing the sample back out to the porous cup during sample recovery. Lysimeters have proven useful to depth in excess of 35 feet. Equipment costs are relatively low, but the equipment requires care and experience in proper installation. Highly saline soil moisture can plug the cup pores as a result of chemical precipitate formation.

REGULATIONS CONCERNING GROUND-WATER QUALITY

In the past few years, a number of regulations have been promulgated at both the Federal and state levels which have an impact on ground-water quality and operations which might endanger such quality. These are briefly discussed below, along with their impact on the technical operation of a facility. They should not be considered as definitive legal discussions, but rather a technical summarization of the various pieces of legislation.

Federal Laws and Regulations

The development of recent ground-water protection regulations has been especially active at the Federal level in the past ten years with the passage of three Acts which severly impact ground-water quality.

The Safe Drinking Water Act has a marked impact on activities which might relate to ground-water quality, as a result of the Underground Injection Control (UIC) program. Many facilities in the metal finishing and electronics industry utilize "dry wells" for the disposal of water such as parking lot runoff. Such "dry wells" are under the purview of the UIC program. At present, such wells are "Class V" wells and are not regulated by permit, but rather are administered under a general rule. However, EPA intends to pursue the appropriateness of regulating the various wells, including "dry wells", which are presently incorporated under the "Class V" designation.

Dry wells do have the distinct potential for contaminating ground-water in those cases where toxic substances are spilled on the pavement, either through drips or by accidental plumbing failure. Thus, there is a need for consideration of the potential contamination associated with the practice of "dry wells".

A few metal finishing operations dispose of effluent by the intentional injection of such waste into deep disposal wells, or Class I wells under the UIC program. The permitting of a Class 1 injection well is quite extensive and expensive and can consume 12 to 18 months between the time of application and permitting.

The Resource Conservation and Recovery Act (RCRA) is a comprehensive bill which pays close attention to the potential ground-water pollution associated with the generation, transport, and especially treatment and disposal of hazardous waste. Regulations promulgated by EPA in response to RCRA specify the number and type of monitor wells which must be emplaced around a hazardous waste disposal facility, and also the type of statistical evaluation of the resultant ground-water quality data. If monitoring under RCRA determines that a contamination situation exists, a phased program of additional, extremely expensive, ground-water monitoring steps must be inaugerated.

The Comprehensive Environmental Response Compensation and Liability Act (CERCLA) deals with the clean up of inactive hazardous waste disposal sites. CERCLA allows EPA to oversee

such clean up and then to charge the costs of such clean up, including EPA administrative costs, to the responsible parties. Under the "joint and several" provisions of CERCLA, EPA can bring enforcement action against any one of a number of responsible parties involved with waste disposal.

Much of the CERCLA activities deal with potential ground-water contamination. The EPA Hazard Ranking System (HRS or MITRE Model) does not incorporate the concept of geochemical attenuation in the subsurface environment. The MITRE Model also does not pay any attention to the direction of ground-water flow, but rather postulates a flow in any direction toward a potential source of supply. While the MITRE Model might be acceptable in a ranking system for organic contaminants in a human environment, it is not pertinent for either metals contaminations or arid zone environments.

State and Local Regulations

In general, the state and local regulations have tended to follow those specified by the Federal legislation. One notable exception is the area of Leaking Underground Storage Tanks (LUST) in which southern California has taken the lead requiring extensive ground-water monitoring around underground storage tanks containing petroleum products or hazardous wastes. Vadose zone sampling techniques are ideally suited for monitoring of LUST.

REMEDIAL MEASURES

Remedial measures aimed at ground-water control can be extremely expensive and time consuming. In general, remedial measures take the form of either recharge prevention, discharge prevention, or recovery and treatment. These general techniques are listed in decreasing order of preference and increasing order of cost. The concept of recharge prevention aims at preventing the movement of either water or contaminants into the subsurface. For example, if the soil in a site is contaminated with mobile contaminants, recharge prevention might take a form such as capping the site with an impermeable clay or membrane cap, or installation of a slurry cutoff wall upgradient of the site, to deflect ground water around the zone of contamination.

Discharge prevention is aimed at preventing the movement of ground water and/or the contaminants from the site. Contaminants may be immobilized by enhancement of geochemical phenomena which tend to provide for fixation. Ground-water discharge itself may be prevented by features such as the emplacement of slurry walls or grout trenches to reduce or retard the movement of ground water from the site.

Techniques for recovery and treatment generally involve capturing the contaminated ground water for pumping to the surface with subsequent treatment and discharge either back to the aquifer which served as its source or directly to surface water sources. Such recovery and treatment can be extremely costly both in capital and operating costs, and must continue until the contamination source has been totally cleaned up. As a result, this can be extremely costly in both time and money.

Appendix A

Summary of Major Geochemical Reactions

By far the single most significant geochemical reaction is that of calcite dissolution, wherein the acidic contaminant reacts with calcite or other carbonate material present in the soil or rock. The reaction is calcite reacting with hydrogen ion to liberate calcium ion and form bicarbonate ion. This results in the gradual downgradient movement of an acidic reaction front, and an acid-front retardation in the saturated zone, relative to the rate of water travel. Hydrogen ions in the acidic plume are consumed by calcite dissolution. The retardation of the advance of the acid front is a result of the number of pore volumes of water with a specified hydrogen ion concentration that must react with a representative volume of the porous media to completely remove the total mass of calcite in the volume (Cherry, Shepherd, and Morin, February 14-18, 1982). Since the rate of ground-water flow is slow relative to the rate of calcite dissolution, the result is a slowly moving displacement acid front.

Calcite dissolution may also take place by means of an anaerobic reaction wherein calcite reacts with ferrous iron to form ferric carbonate (siderite) with the resultant liberation of calcium ion. By this means, calcite reacts with ferrous iron to remove iron from solution by the in place precipitation of ferric carbonate.

Geochemical precipitation pathways are, of course, reversible by dissolution, but in many instances the chemical conditions necessary for the reversal (such as pH of 2) are extremely rare or unlikely in natural geochemical environments (Wilson and Rouse, May 2, 1980). Precipitation of metal hydroxides as a result of increasing pH has been studied by a number of investigators. Rouse (October, 1976) presents a summarization of the process and notes that the various metals are sequentially removed as a result of elevated pH. Figure 1 indicates that iron is the earliest metal hydroxide to be removed as a result of elevated pH values, followed in turn by aluminum, copper, zinc and finally manganese of the common metal contaminants present in the acidic plume. In recent work in the Globe-Miami area of Arizona, several such sequential precipitation plumes have been identified downgradient of copper mining operations (Rouse, in press). Radiochemical pollutants, such as radium, tend to coprecipitate with the metal hydroxides.

Although not commonly recognized, it is possible for hydrogen ions in an acidic contaminant plume to be removed and pH increased by the process of ion exchange, wherein hydrogen ions replace other cations on ion exchange sites such as clay mineral surfaces. This process, while increasing the pH and possibly precipitating other metals, does not reduce the total dissolved solids but rather liberates other major cations and produces an alkali earth-rich solution. However, such major cation

liberation may, in some cases, be countered by the process of gypsum precipitation.

Both the process of calcite dissolution and the ion exchange with clay can result in the presence of high concentration of calcium ions in acidic contaminant plumes such as are common to phosphate acidulation operations. The use of sulfuric acid for many industrial practices results in the presence of extremely high sulfate concentrations. These concentrations of calcium and sulfate ions will, in an aqueous solution, result in the precipitation of gypsum in the subsurface, with subsequent reduction in rock or soil permeability. Note that the precipitated gypsum occupies more volume than the dissolved calcite. Radium has chemical behavior similar to calcium, and hence is coprecipitated with the gypsum.

As was previously noted calcite dissolution can take place by means of calcite reaction with ferrous iron to precipitate siderite. Subsequent to the removal of all calcite mineral from a soil column, this siderite may, in turn, react with acidic contamination plumes to consume acid with the side reaction of dissolution of ferrous iron. This results in the consumption of hydrogen ions and an elevation of pH from an acid plume, but with the undesirable side reaction of dissolution of previously precipitated iron.

All of the above reactions have the desired effect of removing hydrogen ions from solution and raising the pH. Unfortunately, there are a number of competing geochemical reactions which result in decreasing pH by liberation of hydrogen ions.

Some acid contaminant plumes contain high concentrations of ferrous sulfate complex. Such ferrous iron can be directly removed from solution by the oxidation of ferrous iron to the ferric reaction state and the resultant precipitation of ferric hydroxide. The required oxygen can come from dissolved oxygen contained in percolating vadose water, or oxygen dissolved in the ground water. The resultant reaction liberates hydrogen ions, resulting in a pH increase.

Aluminum ion can hydrolize directly with water to form an aluminum hydroxide precipitate, with the subsequent liberation of hydrogen ion. Similarly, aluminum can react with water and dissolved silica to form amorphous alumino-silicate precipitates, with the liberation of significant quantities of hydrogen ion. Evaluation of water quality data in the vicinity of phosphogypsum facilities indicate relatively high concentrations of dissolved aluminum and silica. Thus, it is expected that the acidic plumes may be the site for precipitation of amorphous alumino-silicate precipitates and the generation of additional acidity.

TAILINGS IMPOUNDMENT WATER BALANCES

The following account is excerpted directly from CALDWELL and WELSH (1983). It is interesting that during plant visits, very few of the operating personnel actually are aware of their tailings pond water balance. CALDWELL and WELSH's description provides some insight into how a tailings impoundment water balance is calculated.

Tailings Impoundment Water Balances

Fig. 6 shows the components of a water balance model of a tailings impoundment. As shown, water flows into the system from a number of sources. It is stored within or on the tailings and is lost from the system by evaporation, seepage or discharge. The water balance system or model of an impoundment and mill can be analyzed as three interlinking cycles:

- the mill water cycle;
- the tailings impoundment mill cycle; and
- the tailings impoundment natural cycle.

The first cycle deals with the water input to the mill with the ore, from make-up water and by way of return flow from the impoundment. The tailings impoundment mill cycle deals with water input from the mill, the amount trapped in the deposited tailings and returned to the mill. The impoundment natural cycle deals with rainfall, runoff, evaporation and seepage. It is the only one of the three cycles that deals with stochastic, that is randomly variable, processes. Statistical methods are usually required to deal with this cycle.

Table III summarizes the results of water mass balance studies on three typical tailings impoundments which are either being designed or constructed in the U.S.

Water balance components.

Typical Average Annual Water Balances

Water Balance Item	Case		
	1. Wet	2. Moderate	3. Dry
1. Ore production - tonnes/year	127,000	1,600,000	8,300,000
2. Mill water - L/min			
2.1 Input			
ore	25	170	
fresh make-up	45	60	
tailings return	380	2,000	
2.2 Output			
tailings discharge	450	2,230	
2.3 Mill balance	0	0	
3. Tailings impoundment - mill cycle L/min			
3.1 Input			
tailings discharge	450	2,230	32,200
mine dewatering	7,660	0	3,200
3.2 Output			
trapped in tailings	70	600	3,700
return to mill	380	2,000	35,000
3.3 Mine cycle balance	7,660	-370	-3,300
4. Tailings impoundment - natural cycle L/min			
4.1 Input			
precipitation	1,300	920	4,000
runoff	2,380	1,440	
4.2 Output			
diversion	2,300	650	0
evaporation	170	460	300
seepage	0	0	400
4.3 Natural cycle balance	1,210	1,250	3,300
5. Discharge from tailings impoundment L/min	8,870	880	0

The values listed represent the average annual water volumes over the life of the impoundment. Many of the values vary from year to year and show trends with time. Such details are not shown.

Case 1 is a very wet natural cycle as the precipitation at the impoundment is high. The mill cycle has a large surplus of water from mine dewatering activities; this is discharged into the impoundment. Consequently, a relatively large volume of 8870 L/min must be discharged. Even without the mine dewatering component, the impoundment generates excess water at the rate of 1210 L/min and 70 L/min per thousand tonnes.

Case 2 represents a slightly drier natural cycle. The mill cycle has a slight deficit balance (370 L/min) which means the mill removes more water from the impoundment than it contributes to surface storage. Overall, there is a slight surplus of 0.5 L/min per thousand tonnes which must be discharged.

Case 3 represents a relatively dry natural cycle with a small surplus coupled with a mill cycle which has a slight deficit balance. In this case, a zero total balance has been achieved and the system is, in fact, a closed circuit.

Water balances such as those shown in Table III can be evaluated very easily using regional hydrologic and climatic data, preliminary information on the mill process, and time averaged impoundment and catchment areas.

As the more detailed studies proceed, the mass balances computational process becomes correspondingly more detailed. The tailings impoundment system can be divided into subcomponents such as the main tailings impoundment, the tailings embankment and the seepage return dam. Computer models are used to perform stepwise solutions to the mass balance equations, thus simulating a time sequence that shows how the tailings impoundment develops.

TAILINGS DISPOSAL COST COMPARISON

The following table from WULFF, et al. (1980) shows the relatively wide range in tailings impoundment costs from $1.57 per metric ton to $45.55/metric ton calculated for the disposal of the same tailings at a western U.S.A. site. This indicates the importance of undertaking engineering cost studies for several alternatives. These should, however, be applied using a systems approach. If, for example, below grade disposal was estimated to cost $5.00 per ton compared with $2.50 per ton for conventional above grade disposal, the difference might well be justified if the below ground disposal method avoided the need for a "perpetual" maintenance program and operation of a water treatment plant to treat acid seepage from the tailings in a wet climate; it would hardly be likely to b justified in a dry climate or for disposal of inert tailings where acid mine drainage will not become a problem.

Disposal Alternative	Stage		Range of Costs* Per m^3 (Acre Foot) of Tailings Storage	Range of Costs* Per Metric Ton (Short Ton) of Ore
Total Below-Grade Disposal (Pits or Trenches)	First Stage	High	$ 38.91 ($48,000)	$ 45.55 ($41.32)
		Low	$ 4.31 ($ 5,322)	$ 5.46 ($ 4.95)
	TOTAL	High	$ 4.95 ($ 6,100)	$ 4.55 ($ 4.13)
		Low	$ 4.04 ($ 4,978)	$ 3.64 ($ 3.30)
Combination Below-and Above-Grade Disposal (Cells)	First Stage	High	$ 6.03 ($ 7,434)	$ 6.97 ($ 6.32)
		Low	$ 2.50 ($ 3,084)	$ 1.83 ($ 1.66)
	TOTAL	High	$ 3.84 ($ 4,736)	$ 3.96 ($ 3.59)
		Low	$ 2.49 ($ 3,077)	$ 1.83 ($ 1.66)
Principally Above-Grade Disposal (Single Dam, Head of Valley Impoundment)	First Stage	High	$ 6.35 ($ 7,829)	$ 5.45 ($ 4.94)
		Low	$ 3.76 ($ 4,638)	$ 3.04 ($ 2.76)
	TOTAL	High	$ 3.49 ($ 4,299)	$ 2.85 ($ 2.59)
		Low	$ 2.06 ($ 2,540)	$ 1.57 ($ 1.42)

*Costs used to develop this table include capital costs for all applicable features of a given disposal scheme, excluding tailings and water conveyance facilities.

CLOSURE OF MILL TAILINGS

Closure of mill tailings impoundments at the end of an operation is critical. How this is achieved could well determine whether a perpetual maintenance program with acid mine drainage treatment plant is required or not. How a tailings impoundment site can be restored largely depends on how it was designed in the first place and the nature of the tailings.

The greatest single environmental problem facing the mining industry today must certainly be acid mine drainage control, i.e., the disposal of wasterock and mill tailings that contain sulfide minerals, particularly after the milling operation has ceased.

BLIGHT and CALDWELL (1984) state, in connection with Witwatersrand tailings disposal sites, "It became abundantly obvious during these investigations that no maintenance-free solution exists to the abatement of pollution from abandoned dams. Maintenance efforts can be minimized by careful design and construction, but the onslaught of the elements ensures that maintenance and aftercare can never be eliminated."

Discussion of several aspects of tailings site stabilization and revegetation is included in the following excellent papers. Sponsors are also referred to trip reports on the Wedge

Mine, INCO at Copper Cliff, Waite-Amulet site in Quebec, as well as Falconbridge at both Falconbridge and Onaping, Ontario, for additional discussion of site restoration in Appendix I.

Despite BLIGHT and CALDWELL's conclusion, and the same basic conclusion drawn in the course of this investigation, it is a worthwhile goal to set, i.e., development of a method of disposing of tailings and restoing the site to avoid the need for future perpetual maintenance and, especially, for effluent treatment.

This discussion brings to mind the Atlas Minerals tailings site alongside the Colorado River at Moab, Utah. When looked at philosophically, perhaps the cleanest and safest way to permanently dispose of those tailings would be to let them wash down the Colorado River the next time it comes down in flood. When in flood, the municipal water plants downstream shut down anyway, and the ultimate destiny of the tailings would be in a thin layer of sediment spread across the floor of the Boulder Dam. That would solve all safety, environmental, and aesthetic aspects of these otherwise unattractive tailings.

In Canada, the revegetation of highly acidic iron sulfide-rich tailings has been accomplished by trial and error, largely to reduce the dust and aesthetic problems. At INCO, Sudbury, very large areas of reclaimed tailings are planted with grass and harvestable crops annually and, in effect, the reclaimed tailings have been converted into farmland. This type of vegetation is, however, not self-sustaining. Neither of these have yet proven to inhibit AMD generation in the underlying tailings, however.

At Waite-amulet, Noranda has achieved a lush, dense vegetation cover which is self-sustaining year after year, directly over a high iron tailings site.

Falconbridge, at the Onaping and Falconbridge sites in Ontario, have used crushed wasterock as a capillary barrier over high sulfide tailings in some cases; in others, town garbage and sewage sludge is used over the capillary barrier; and in yet others, low sulfide tailings are applied as a cover over the high sulfide tailings before revegetation.

At not one site visited is there yet evidence of a sulfide-containing tailings pond which could be left unattended without the need for site maintenance and/or installation of a water treatment plant, although progress is being made in that direction.

JONGEJAN and RITCEY (1981) described a way to produce compost from municipal wastes of Canadian Mining towns which could be used for enhanced revegetation of mill tailings sites.

The abatement of pollution from abandoned gold-residue dams

by G. E. BLIGHT* and J. A. CALDWELL†

SYNOPSIS

The metropolitan area of the Witwatersrand has grown up around the Witwatersrand gold mines. Most of the mines have now been abandoned, but deposits of waste material remain and have been surrounded, and in some instances covered, by urban and industrial sprawl.

This paper describes the development of geotechnical measures for the abatement of air and water pollution from abandoned gold-residue dams in the Witwatersrand area. The measures include the stabilization of the surfaces of the dams to prevent wind and water erosion, the terracing of slopes to minimize erosion, and the construction of catchment walls and dams.

The measures were developed in terms of the set of guidelines for environmental protection adopted by the Chamber of Mines of South Africa in 1979.

SAMEVATTING

Die metropolitaanse gebied van die Witwatersrand het om die Witwatersrandse goudmyne gegroei. Die meeste van hierdie myne is tans verlate, maar die afsettings van afvalmateriaal is steeds daar en is deur wydlopige stedelike en industriële uitbreiding omring, en in sommige gevalle selfs daardeur bedek.

Hierdie referaat beskryf die ontwikkeling van geotegniese maatreëls vir die vermindering van lug- en waterbesoedeling afkomstig van verlate goudresiduddamme in die Witwatersrand-gebied. Die maatreëls sluit in die stabilisering van die oppervlakte van die damme om wind- en watererosie te voorkom, die aanlê van terrasse teen hellings om erosie tot die minimum te beperk en die bou van keermure en opvangdamme.

Die maatreëls is ontwikkel in terme van die riglyne vir omgewingsbeskerming wat die Kamer van Mynwese van Suid-Afrika in 1979 aanvaar het.

Introduction

Unlike the United States of America and Canada, the Republic of South Africa has no legislation specifically directed towards the protection of the environment from the effects of mining. However, there are a number of statutes that affect the design, operation, and abandonment of residue deposits. These are the Atmospheric Pollution Prevention Act, the Health Act, the Mines and Works Act, the Soil Conservation Act, and the Water Act. To comply with the requirements of these Acts and to achieve effective environmental control over the tailings deposits owned by its members, the Chamber of Mines of South Africa in 1978 commissioned the authors to draft a comprehensive set of guidelines for the design, operation, and closure of tailings deposits[1]. These guidelines were revised in 1983.

After a brief description of the guidelines pertaining to the closure and aftercare of tailings deposits, this paper describes measures put into effect to bring a number of abandoned gold-residue dams in the Witwatersrand area into compliance with the guidelines. The measures incorporate a number of interesting features. First attempts at compliance with the guidelines were based on tried and tested, but conventional, geotechnology. Because of the characteristics of gold slimes, the measures met with mixed success. Apart from describing the protection measures, the paper recounts the difficulties experienced and points to solutions to these difficulties.

It became abundantly obvious during these investigations that no known maintenance-free solution exists to the abatement of pollution from abandoned dams. Maintenance efforts can be minimized by careful design and construction, but the onslaught of the elements ensures that maintenance and aftercare can never be eliminated. The present paper represents an amplification and updating of an earlier paper on the subject[2].

Guidelines for the Closure of Tailings Deposits

The guidelines for the closure of tailings deposits require, prior to the closure of any tailings deposit, an inspection to be made by a professional engineer, who should report on the existing state of the deposit and list all the actions that are needed to ensure that the deposit complies with the provisions of the guidelines. In addition to the state of the tailings deposit itself, the report should note the presence of any adjacent structures or development, and the extent to which they may be affected by abandonment of the deposit. Recommendations to minimize the impact of abandonment or of possible failures of the deposit after abandonment should also be made.

Erosion of Top Surfaces

The Atmospheric Pollution Prevention Act requires that steps be taken to prevent the dust from any waste deposit becoming a nuisance as a result of its dispersion in the atmosphere. Regulations under the Mines and Works Act require that any waste deposit be dealt with in a satisfactory manner so as to prevent the dissemination of dust or sand from it. The Water Act requires all rain water precipitated on a waste deposit to be retained on that deposit, together with any of the waste material that becomes displaced by the action of the precipitation. To comply with these requirements, the guidelines require the best practicable means to be adopted to

prevent erosion of top surfaces. Among the measures that have been suggested for the control of wind erosion are the following:

(a) the establishment of vegetation on the top of a deposit, either by planting directly into the tailings material or by first covering the surface with a layer of top soil of suitable thickness (the cost of importing topsoil usually rules out the latter alternative);

(b) covering the top of the deposit with a suitable thickness of broken waste rock.

Water erosion on top surfaces, as well as the requirement that all precipitation should be held on the dam, has been taken care of by a system of crest walls that sub-divide the surface of the dam into a series of paddocks. The crest walls also prevent precipitation on the top of the dam from cascading down the outer slopes and increasing the potential for slope erosion. The height of the crest and division walls is designed hydrologically so that the walls contain the maximum probable precipitation over a period of twenty-four hours with a frequency of once in a hundred years*. A freeboard of 0,5 m is required throughout the system above the predicted maximum water level. In the Witwatersrand area, as the annual evaporation from a free-water surface vastly exceeds the annual precipitation, there is usually no need to decant water from the top surface of a deposit.

The paddocks must be carefully shaped to prevent water from standing near the crest wall of a dam. Numerous cases of piping erosion[3] have occurred when water has been held on the surface near to the crest of a dam.

The penstocks used to decant water during the operation of a residue dam are plugged when the dam is closed because they otherwise tend to collapse and provide channels for piping erosion. Old dams often have a number of steel delivery or penstock pipes buried in them at various positions. The steel has usually corroded away and the resulting void been enlarged by erosion. Such a collapsed pipe can result in severe erosion, as illustrated in Fig. 1.

In practice, water and wind erosion are inextricably linked. Material loosened and collected in low spots by water erosion in the wet season may be picked up by the wind and dispersed as dust during the dry season.

Erosion of Slopes

The slopes of old residue dams are extremely steep (usually 35° or more), and the protection of these steep slopes against erosion is very difficult. Sheet erosion of the slopes can be reduced, and gulley erosion virtually eliminated, by the provision of crest walls, which prevent water from cascading off the top and down the slopes of a residue deposit. Slopes can be protected against erosion by being covered with a layer of waste rock. However, this requires a large quantity of rock because the angle of repose of the rock seldom, if ever, equals the slope angle. Vegetation has also been used to provide protection against erosion. This practice has not proved entirely successful: some of the steeper slopes are gradually denuded of grass as erosion progresses.

Fig. 1—Severe erosion caused by the collapse of steel penstock and delivery pipes buried in the residue. Voids left by a number of such pipes are visible

Containment of Precipitation and Eroded Material

Run-off and eroded material are contained by a series of catchment paddocks round the perimeter of a dam. These paddocks are designed hydrologically to ensure a freeboard of at least 0,5 m above the maximum predicted water level, which is based on the average monthly rainfall for the area concerned less the gross mean evaporation for the area plus the maximum precipitation to be expected over a period of twenty-four hours for a frequency of once in a hundred years. To this is added an additional capacity to allow for the siltation resulting from erosion off the slopes. Little information exists on rates of siltation, but it appears that, in extreme cases, a single storm can silt a paddock to the extent of encroaching on the freeboard, whereas more usually the siltation capacity is a number of years. Regardless of the actual siltation rates, provision must always be made for the desiltation of paddocks, or raising of their walls, once the required freeboard is no longer adequate.

Control of Access

It has been found essential to prevent access to abandoned tailings deposits by members of the public,

*On the Highveld, this is equivalent to 250 mm of precipitation.

especially those seeking recreation by horseriding or cross-country motor cycling. The trails left by these activities often reduce the freeboard of paddock walls and result in gulley erosion. It is therefore considered essential that each abandoned tailings deposit should be surrounded by a properly constructed, well-maintained security fence. Cutting of fences, and even the theft of whole sections of fencing, gates, etc., are common. Hence, frequent inspection and maintenance are essential if unauthorized access is to be prevented.

Stability of Slopes

The retention of water on the top surface of a tailings deposit, as well as measures such as erosion protection by the covering of slopes with rock, may lead to instability of the slopes.

The guidelines require an investigation of potential slope instability as part of the closure report.

Fig. 2 shows diagrammatically some of the features mentioned above, while Fig. 3 shows the crest and dividing walls on the top of an abandoned dam. (Note the urban development surrounding the dam and the severe surface erosion in the foreground.)

Fig. 2—Diagram showing measures taken to minimize water erosion of abandoned tailings dams

Geotechnical Developments in Pollution Abatement

A considerable number of abandoned gold-residue deposits exist within the Witwatersrand metropolitan area. The area has been almost completely built up, and the tailings deposits in question are surrounded by residential and industrial development. In most instances, the mining companies responsible for the tailings deposits are defunct, and the State has accepted responsibility for the rehabilitation of these dams to comply with the Chamber of Mines guidelines. To date, more than twelve dams have been rehabilitated. During the course of the work, a number of rehabilitation features were developed that differ from those envisaged when the guidelines were prepared. While the authors are convinced that the principles on which these measures were designed are correct, their implementation has not been completely successful, for a number of reasons. These measures and their shortcomings are described below, together with possible remedies.

Cement Stabilization of Top Surfaces

The Chamber of Mines considers the vegetating of the top surfaces of dams to be the best practicable means of stabilization, but this is subject to certain difficulties. The lack of success can be partly ascribed to the low pH of the surface material, and wind action may also undermine the root systems of the vegetation. Estimates by the Chamber of Mines at the time at which the guidelines were being prepared (1978) indicated that vegetating and the associated maintenance was costing upwards of R10 000 per hectare, while the cost of importing soil or waste rock was prohibitive, quite apart from the limited availability of these materials.

For these reasons, the chamber decided to stabilize the top surfaces of a number of dams on an experimental basis, using either slaked lime or Portland cement. Although the gold mine tailings that were being dealt with were highly acidic (pH of 3,5), Eades tests showed that relatively little stabilizer was required to raise the pH to a stable level of approximately 12,5. Fig. 4 shows typical results of Eades tests with ordinary Portland cement. It is also known that, although gold residue contains no clay minerals, it does contain a certain amount of amorphous silica, which can be expected at pH values above 12 to react with hydrated lime to form calcium silicates. The ability of slaked lime to stabilize residue sands had earlier been demonstrated when the surface of an access road to a sand dump near the Johannesburg market was stabilized. The surface remains in a remarkably good condition a decade and a half later, although the lime content of the material is very high. It was considered that stabilization should be even more effective with the gold slimes, which are finer.

In the case of cement stabilization, it was realized that sulphates contained in the residue might attack the products of cement hydration. However, at pH values above 12, the sulphates should be in the form of gypsum which, being sparingly soluble, is not as aggressive as other forms of sulphate. The use of sulphate-resisting cement could not be contemplated owing to its high cost. Because it is essential to keep the costs of rehabilitation as low as possible, and also because the object was the achievement of an erosion-resistant skin on the surfaces of the tailings deposits without the achievement of much strength, it was decided that experiments should be conducted with very small stabilizer contents.

Accordingly, a series of large test panels measuring 30 m in length by 5 m in width and stabilized to a depth of 150 mm were laid out using 2, 3, and 4 per cent by mass of both lime and cement. After the required quantity of stabilizer had been spread on the surface of the tailings deposit, it was mixed in by use of a rotary mixer. The moisture content was then adjusted to the optimum for compaction, and the panels were compacted by pneumatic rolling. The completed stabilized panels were

Fig. 3—Abandoned tailings dam provided with crest and dividing walls

moist-cured for six days by use of water sprays. The erosion resistance of the stabilized tailings surface was assessed with a portable Comet erosion tester, which directs a jet of water 0,8 mm in diameter at the surface from a distance of 25 mm. The pressure behind the jet is increased at a steady rate until the surface breaks up, the pressure at which the disruption occurs being recorded as a measure of the erosion resistance. The authors do not consider the Comet tester to be ideal for the measurement of the erosion resistance of residue surfaces. It gives a point measurement that, in their view, is not representative of the erosion resistance of a surface of large extent. Moreover, the relationship between the Comet index and actual rates of erosion has not yet been established.

Fig. 4 shows the measured erosion resistance plotted against percentage cement at times of 21 days, 42 days, and 2 years after stabilizing. It became apparent from these results that (at least in the early ages) cement was more effective than lime, and it was decided that the top surfaces of a number of tailings dams should be stabilized with cement (3 per cent) to a depth of 75 mm, and that the performance of these surfaces should be observed over a number of years. Twelve tailings deposits were stabilized in this way.

The test results in Fig. 4 show a considerable decrease in Comet readings after 2 years. The decrease can be attributed to at least two causes:

(i) the attack on the cement by sulphates proved to be more severe than expected; and

(ii) soluble salts, drawn to the surface by evaporation gradients and crystallizing out at the surface, disrupted material at the surface.

These effects may reinforce each other. Rising salts and acid may result in a lowering of pH and, hence, an acceleration of the attack by sulphates.

The Comet resistance of lime-stabilized panels showed a similar decrease after two years to that for cement-

Fig. 4—Results of tests on the stabilization of gold residue with Portland cement

stabilized panels. As attack by sulphates can be ruled out in the former panels, disruption by salt crystallization and acid attack appear to be the major causes of the deterioration.

A visual assessment of the surface condition of twelve dams that had been stabilized with cement shows that similar deterioration has occurred there. 'Fluffy', raised surface crusts resulting from salt crystallization are much in evidence. The surface finish appears to be more important in maintaining erosion resistance than was previously appreciated. The smooth, almost-glazed surface

Fig. 5—Appearance of test panels of stabilized gold residue three years after laying

Fig. 6—Appearance of paddock walls protected against wind and water erosion by a single layer of 19 mm of crushed-stone chips. Photograph taken two years after laying

produced by a pneumatic compactor appears to deteriorate less than the rough, indented surface left by a tamping compactor. Fig. 5 shows the surfaces of the original test panels three years after being laid. The unstabilized strips between the panels show up as a result of their lighter colour. Even though the Comet resistance of the panels is low, they now stand proud of their surroundings, showing that they are more erosion-resistant than the unstabilized surfaces.

The effect of the surface deterioration is that loosened material is washed into the low spots of the paddocks during the wet season. Although this material crusts over as it dries, it is potentially available for dispersion by wind during the dry season if the crust is disturbed.

Successful alternatives to stabilization with cement or lime are not obvious. Potentially the most successful alternative is a process that was used for the stabilization of travelling sand dunes outside Walvis Bay. There, a

large dune that threatened to move into the town was successfully halted after its surface had been covered with power-station cinders. The layer was thin, only one particle thick, but successfully prevented the wind from picking up the underlying sand, thus halting the movement of the dune. This technique was tried on the slopes of the paddock walls of one of the twelve treated dams. There, a single-particle layer of 19 mm crushed-stone chips was spread on the slopes. Two years later, the treatment appears to have been very successful, with little evidence of the displacement of the stone or the underlying slimes by water or wind. Fig. 6 shows the appearance of this treatment two years after its application.

Grassing of Residue Deposits

Greig[4], from a study of the vegetation established on 27 slimes dams in the Central Witwatersrand area, concluded that, in general, the ratio of grass cover to slime exposure is 1 to 2 or greater, and that this cover ratio approaches that of the natural veld. He notes that there is no evidence that wind or water erosion from horizontal surfaces grassed up to fifteen years ago is a problem. The cost per hectare of grassing, leaching, and maintaining the top of a slimes dam where only the perimeter and contour wall are leached varied at that time from R3836 for a 40 ha site to R9321 for a 4 ha site. When the whole surface was leached, these costs increased to R10 024 and R14 859 respectively.

The average cost of cement stabilization at the twelve deposits so treated varied from R5000 to R8000 per hectare.Thus, the costs for the two types of treatment were similar at that time.

Terracing of Slopes

At a number of locations, the authors had observed that, where vertical faces had been cut in the slopes of tailings deposits, these faces appeared to be unaffected by erosion. The same phenomenon has been observed in natural vertical slopes. It was therefore decided that an experiment should be carried out in which the slope of a tailings deposit is terraced into a series of vertical faces separated by approximately horizontal steps or berms. To retain the precipitation, the berms are sloped back towards the dam, and are sub-divided at intervals by cross-walls so that all the precipitation on the berms is held and allowed to evaporate. Fig. 7 gives a design section of a terraced slope, and Fig. 8 shows an experimental terraced slope three years after the terraces were cut.

Fig. 7—Design section for terraced slope shown in Fig. 8

The state of these terraces is extremely good. In all cases very little erosion of the vertical faces has occurred, and in many cases a hard, dry crust has formed on the vertical face. Some eroded slime has accumulated in the paddocks formed by the back-sloping benches, and in a few instances exceptionally heavy rain has resulted in

Fig. 8—Experimental terraced slope three years after the terraces were cut

Fig. 9—Vertical face of a terrace taken three years after the terrace was cut

overtopping of the benches. Fig. 9 is a close-up view of the vertical face of a terrace, showing the excellent condition of the surface.

On the basis of the observed behaviour of the terraces, it is concluded that terracing is a very effective way of reducing erosion from the slopes of residue dams.

Filter Dams

Run-off from tailings deposits that is polluted by material eroded from the deposit is retained at strategic positions by dams designed to retain the silt content of the run-off while allowing clear water to seep away. Although this water is clear, it contains dissolved solids, and only one component of pollution is removed. Fig. 10 shows typical details of such a filter dam. The upstream slope of the dam is underlain by a filter blanket that acts as a collection drain and filter for the polluted water retained behind the dam. After entering the filter blanket, the water gravitates to the central collecter drain and is allowed to escape downstream. Fig. 11 shows one of these dams, together with its emergency spillway, protected from erosion by means of a gabion mattress.

Fig. 10—Plan showing details of a filter dam

Fig. 11—Appearance of a filter dam with an emergency spillway

Fig. 12—Failure by piping erosion of a filter dam constructed of gold slimes and built on a slimes foundation

No problems have been experienced with these dams where it was possible for them to be constructed of natural soil. However, when constructed of gold slimes, especially when built on a foundation of slimes, numerous problems have been experienced with piping erosion. Erosion pipes have formed in the slimes under the dams, at the contact between the dam and the abutment, and at the interface between the embankment material and the geofabric-wrapped filter. Laboratory tests have shown that the erodibility of slimes is much reduced if the pH is raised to above 12 and the material cemented by the addition of lime. Future embankments should be constructed of lime-treated material. In addition, the embankment must be keyed into its abutments and foundation to lengthen the seepage path of potential pipes. Fig. 12 shows typical piping-erosion damage to a filter dam constructed of gold slimes and having slimes abutments.

Fig. 13—Section through geofabric-reinforced gravity-section filter dam

Fabric-reinforced or Cement-stabilized Dams

In rehabilation work on tailings dams, it often occurs that a narrow valley with a limited capacity has to be crossed by a filter dam. If a conventional dam of compacted tailings is constructed, too much of the capacity of the valley is occupied by the filter-dam embankment. In situations like this, it is advantageous for the dams to have steeper slopes and, in fact, a gravity section is ideal in such instances. A gravity-section dam can be built either of cement-stabilized tailings or of fabric-reinforced tailings.

Fig. 13 shows the design of a fabric-reinforced gravity-section embankment. This embankment has been built and is illustrated by Fig. 14. The dam spans a valley between two tailings deposits down which a natural stream flows. The stream has been by-passed through a culvert that runs down the valley and under the gravity-section dam, while the gravity-section dam itself acts as a filter dam for precipitation running off the slopes of the tailings dams on either side of the valley.

When first filled, an erosion pipe large enough for a man to crawl through formed through the lower part of the dam abutment. The entry to the pipe is clearly visible in Fig. 14. The fabric-wrapped embankment bridged over the pipe with some deformation but was otherwise undamaged, as the photograph shows. The failure was repaired by the placing of a filter blanket over the hole on the upstream side and plugging of the hole with compacted tailings from the downstream side. The authors consider that any less flexible construction would have failed completely.

Aftercare of Tailings Dams

It must be recognized that the environmental protection measures specified by the guidelines of the Chamber of Mines require continual inspection and maintenance if they are to remain effective. There is no maintenance-free solution to the environmental protection of tailings dams.

(1) Any erosion damage to crest or dividing walls, filter dams, or catchment paddocks must be repaired.

(2) Catchment paddocks and filter dams must be desilted periodically, or must be raised in order to maintain their capacity.

(3) Continual inspection must take place lest problems of slope stability, the collapse of old drainage conduits, or penstock outfalls and similar degeneration should cause breaches in the anti-pollution defences of the protected dam.

(4) Access by animals and the public must be prevented. This last requirement contains something of a sociological problem. The existence of the large, abandoned, inaccessible areas represented by environmentally protected tailings dams within urban environments makes them attractive, not only as playgrounds for early-teenage children, but also as hiding places for the lawless element of the community.

(5) Dumping of litter adjacent to abandoned tailings dams is another social problem to which there appears to be no solution at present but periodic clean-ups.

Fig. 14—Geofabric-reinforced dam after the formation of a pipe through the foundation. The entrance to the pipe can be seen to the right of the dam

Even though there is no common method for establishing vegetation for tailings, a high degree of scientific and technical expertise is required to ensure a successful reclamation program Here are some ideas on how to implement successful programs

Tailings reclamation in eastern Canada

By **Dr. Edward M. Watkin**
and
Jo-Ann Watkin
Mine Waste Reclamation Ltd.
565 Massey Road
Guelph, Ontario
Canada

Vegetation establishment on tailings in Canada has received widespread attention in the past decade. In Canada, few hard rock mine and mill waste products are considered to have any land use potential other than for wildlife purposes.

Isolation from densely populated regions and intensively farmed areas generally precludes development for recreational, agricultural, and commercial purposes. Specific characteristics of waste disposal areas, such as radionucleide contamination in uranium tailings, or physical site dangers represented by steep slopes of nearby "glory holes" are often sufficient reason to justify exclusion of the public from these areas.

Numerous studies have demonstrated considerable heterogeneity both within and between tailings disposal areas for all forms of metal mining. It is now recognized that a high degree of scientific and technical expertise is required to ensure a successful reclamation program.

Unfortunately, there is, from an industry viewpoint, no common method for establishing vegetation; every tailings disposal area requires individual assessment. Prime importance is now given to establishing vegetation directly into the tailings and not to covering with overburden—a technique of last resort.

For the majority of companies, reclamation by revegetation must veer toward a simplistic concept—the establishment of a permanent, self-sustaining and maintenance-free plant cover, which will achieve one or more of the following ends:

- Fugitive dust control
- Erosion control to prevent dam wall rupture
- Erosion control to prevent run-off of surface particles and subsequent sediment disposition in water courses
- A reduction in water volume seeping through acid and heavy metal contaminated wastes
- Aesthetic improvement of waste areas
- Acceleration of natural succession on waste areas.

Laboratory and field experience has established the following general principles for developing a tailings reclamation program:

- The need to form a reclamation team comprised of personnel with expertise in agronomy, engineering, hydrology, milling, and water quality
- To allow at least 2 years, preferably longer, for the development of an overall tailings abandonment program so that the necessary procedures can be developed and evaluated prior to implementation to ensure the most efficient cost selection
- To realize that a vegetation program is a biological system, subject to failures as well as successes, the causes of which cannot necessarily be predicted by "slide-rule" calculations
- The understanding that such a program requires the same intensive technical input as any other portion of a mining operation and, if not treated as such, will be subject to expensive failures.

Early Programs

One of the earliest tailings reclamation projects in Canada was that undertaken at Timmins, Ontario by McIntyre Mines Ltd. (now Schumacher Division-Pamour Porcupine Mines Ltd.) in 1932. Fertilizer and black muck were worked into non-sulphide gold tailings, and clover and timothy were planted to create a local park.

Several years later, tree planting and formal landscaping took place. In the same period the Hollinger Mine also embarked upon a tailings reclamation program using techniques similar to those of McIntyre. Today some tailings sections on this site have been built upon for commercial purposes.

Starting in 1968-69 all the operating mines in the Timmins region began tailings reclamation programs. Those involved at the time were Broulan-Reef Mines Ltd., Dome Mines Ltd., Hollinger Consolidated Gold Mines Ltd., Preston East Dome Mines Ltd., the Noranda group of companies, and Kidd Creek mines of United States-based Texasgulf Inc.

Many programs continue today, accepted as part of normal operations.[1]

The Birdsfoot Trefoil

Significantly, all these later programs contained a common ingredient for success, the legume birdsfoot trefoil (*Lotus corniculatus*). Since the early 1970's birdsfoot trefoil has formed the cornerstone of all successful reclamation programs for acidic, neutral, and slightly alkaline tailings.

This legume has widespread adaptation to tailings moisture conditions, is winter-hardy in most of the country and forms a self-sustaining and maintenance-free plant cover. If seeded in conjunction with correct fertilizer practice and specific grass species, no additional agricultural inputs are required from the day of seeding.

Where establishment has not been satisfactory, this can be attributed to incorrect fertilizer practice, its inclusion in unsuitable multiple species grass seeds mixtures, or poor bacterial inoculation technique.

General experience has shown that other legumes are not suitable for many tailings reclamation programs. Alfalfa, and white, red, and alsike clovers do not provide the self-sustaining and maintenance-free aspects that characterize the use of birdsfoot trefoil.

Crownvetch, while exhibiting many desirable characteristics, has not been used due to inconsistent establishment and high seed cost.

The first successful reclamation of sulphide tailings was achieved by the International Nickel Company (Inco) of Canada in the mid-1960's after almost 15 years of investigation, although the

company's general area reclamation program dates back to 1917. Numerous techniques were investigated before success was achieved; a technique permitting seeding of grasses direct into the tailings.

Methods and materials developed by Inco were almost immediately adopted by other mining companies, generally with poor results. As subsequent investigations have shown, each and every sulphide tailings area requires its own particular set of methods and materials.

In terms of iron sulphide content, the tailings deposited by Inco are now classified as low. The majority of the acid-producing iron sulphides (pyrite and pyrrhotite) in the original ore are moved during ore processing.

As the results of attempts to reclaim other tailings areas that had been formed by the milling of massive sulphide ore bodies were obtained, showing FeS content between 5 and 45 percent, it became obvious that new approaches and techniques would have to be developed for such areas if revegetation by direct seeding was to be successful.

pH and Tailings

As the environmental importance of acid tailings seepage was established in Ontario[1], and subsequently in eastern Canada, two companies developed major reclamation programs.

The Horne Division of Noranda Mines Ltd., in Noranda, Quebec, mining a massive sulphide deposit, expanded its work into a five-year research program at a Canadian university.

Rio Algom Ltd.'s Elliott Lake, Ontario uranium operation set up a program in cooperation with Canada Ener-

gy, Mines, and Resources.

Both of these programs attempted to correlate physical and chemical tailings characteristics with plant growth obtained in controlled environment studies. Neither was successful in this.

For example, under the auspices of the Noranda Mines (Horne Division)-University of Guelph research program, "Reclamation of Mine and Industrial Wastes," an attempt was made to correlate such factors as mineralogical analysis of iron sulphide content and form, other mineral constituents, X-ray analysis of heavy and light mineral fractions, X-ray analysis of water soluble constituents, chemical analysis of water soluble constituents, acidity of tailings and standard agricultural soil test analyses of a wide range of oxidized and non-oxidized tailings, with plant growth performance on such tailings.

No definite correlation was found between the above factors and plant growth potential. Only the total salt content of tailings provided any degree of correlation, but even in this case the variability was too great to be of any practical significance.

These studies, as well as others that were conducted by Mine Waste Reclamation, have confirmed the unreliability of present analytical procedures. Determination of the agricultural limestone requirement of acidic tailings by using plant growth as an indicator has revealed an enormous variation both within and between tailings disposal areas (see Table 1 and Figure 1). That variation cannot be correlated with the pH values obtained for the samples as depicted in Table 2.

The measurement of pH in tailings can only be approximate. Apart from the fact that there are no detailed research studies on what might be the most accurate method of measurement, even using any one constant method for determination will show that pH values vary considerably at any sample point in a single growing season.

At present, pH measurement should be considered only as a broad indication of the presence or absence of potential problems in the establishment of a vegetative cover.

Limestone Quality

Another problem shown in recent studies is concerned with the quality of agricultural limestone. In studies conducted under the previously mentioned Noranda-Guelph program and by Mine Waste Reclamation, a single source of agricultural limestone was and is being used to determine the amounts required to amend acid tailings so that vegetation can be established. In the field, agricultural limestone would be obtained from numerous sources, depending upon mine site location.

A standard evaluation was made of agricultural limestone in 1980-81. Understandably, the limestones vary widely in physical and chemical composition and in their efficacy as neutralizing agents (see Table 3).

It is not possible to select agricultural

Table 3.
Variation in agricultural limestone

Character	1	2	4	5	6	8	9	10
Percent passing 5 mesh	100	100	37	62	100	—	100	
10 mesh	97	100	20	36	98	100	90	100
60 mesh	80	26	5	6	35	100	40	86
100 mesh	52	12	4	4	24	86	30	59
Percent total calcium	35	21	30	26	24	29	54	30
Percent total magnesium	3	0.2	0.3	0.2	4	0.3	45	0.2
Neutralizing value (pure $CaCo_3$ = 100)	84	100	84	93	92	91	100	94
Agricultural index[1]	73	56	9	17	55	91	60	86

[1]Agricultural index is a value calculated from percent passing 10 and 60 mesh and from neutralizing value. For agricultural purposes an index of 75 or above is generally recommended; it is not necessarily recommended for use on acid sulphide tailings where an index as low as 55 has proven suitable.

Agricultural limestone requirement (tons per acre) **Figure 1**

limestone solely on the basis of desirable characteristics and efficacy. Transportation costs preclude such choice. It is necessary, though, to give some consideration to the characteristics of the available material.

For example, material from sources 4 and 5 are too coarse as evaluated but would be suitable if they could be ground to finer particle size; whereas, source 8 is considered to be too fine, both in terms of applying it in the field and lack of sufficient coarseness to provide long-term buffering capacity.

The level of phosphorous fertilizer used in both laboratory studies and field programs has been found to be critical, particularly in obtaining adequate legume establishment. On one medium sulphide tailings area (Site 9A, with 45 percent FeS), where a wide range of agricultural limestone was required (see Figure 2), and where soil test analyses indicated virtually no phosphorous present, striking responses were obtained to phosphorous application (see Table 4).

A base fertilizer of 1,500 pounds per acre 5N-20P-20K was applied with additional treatments of nil (low), 500 pounds per acre ON-46P-OK (medium) and 1,000 pounds per acre ON-46P-OK (high). A vegetative response was still recorded at the highest level of phosphate application.

Neutral non-sulphide gold tailings when seeded with birdsfoot trefoil alone also showed a high level of growth with increased phosphate. Because of the nitrogen fixation capacity associated with legumes, this increased growth is most probably due to the interaction between nitrogen and phosphorous and its effect on plant growth, a well-established phenomenon.

Tall fescue, which like most grasses does not have this nitrogen fixation capacity, does not respond to additional phosphorous when seeded alone. While emphasizing the effect of phosphorous on plant growth, the studies have also demonstrated that fertilizer requirements for plant growth are also species-dependent.

The widespread variation in agricultural limestone requirement exhibited both between and within tailings disposal sites and disturbed land areas is possibly a reflection of several factors, such as iron sulphide type and quantity, degree of oxidation of iron sulphides, distribution of tailings grain size in the tailings ponds, length of inundation of water on the tailings surface, and mineralogical composition of the ore body.

Site 9A requirements (tons per acre) **Figure 2**

At the present time it is not possible to determine the interrelationships between these factors by analytical means. It does mean, though, that a tailings disposal area is in most instances a very heterogenous area, with widely different plant growth potentials across its surface. Because of that variation, it is virtually impossible to conduct small plot trials in the field in order to determine plant growth potential.

To assess the surface variation and its varying requirement for agricultural limestone, fertilizer requirement, and suitable species would entail very extensive field plot work. In addition, such trials may take 18 months or more to complete, as at least two growing seasons would be required for a comprehensive evaluation.

If such trials were to take into account additional factors such as optimum seeding time, method of seeding (mechanical and hydroseeding), evaluation of different mulches, and their rates of application, then the field trials would become even more complex.

Without doubt, several field trials could be conducted in place of one large one. Such an approach, though, inevitably lengthens the evaluation period to at least 3 to 4 years, for until the basic requirements for vegetation establishment are known, factors such as time of seeding, mulch requirements, and other practical aspects cannot be adequately assessed.

Sampling

One approach to resolve the apparent complexity of field type evaluation that is finding increasing acceptance is to evaluate initial vegetation potential under controlled environment conditions. The basis of this technique is to take samples from a tailings area, then sample the selection being governed by visible variation on the tailings surface such as color (degree of oxidation), particle size, and different moisture levels.

Such sampling is subjective, but is the only known means at present. This particular approach has several important advantages over beginning the evaluation directly in the field.

Evaluation time is reduced to approximately 100 days, compared to 18 to 24 months. The evaluation concentrates on determining the optimum agricultural limestone and fertilizer specifications and results in the elimination of much subsequent field plot investigation.

Not all tailings or disturbed soils have an immediately recognizable vegetation potential. That may be due to the very high agricultural limestone levels required, which may be too costly, particularly if the agricultural limestone sources are distant or to an inherent low potential, which can only be increased by devising other methods of amendment.

Whatever the reason, a company rapidly becomes aware of the degree of ease or difficulty it will face in conducting the vegetation aspects of a rehabilitation program. If the evaluation indicates an acceptable level of vegetation potential, then the first field trials to be conducted can concentrate on the practical field aspects of vegetation establishment, unhampered by uncertainty as to whether or not the correct amendment levels have been chosen.

Such evaluation enables a company to rapidly assess the future financial aspects of the vegetation portion of the rehabilitation program, and at a cost considerably less than that required for conducting a two to three-year field testing program.

Reclamation programs utilizing the above approach are now being undertak-

en by a number of Canadian mining companies (see Table 1). Some programs are almost completed, others are still at the assessment stage prior to considering field trials, and others are presently in abeyance.

At Noranda-Horne, about 100 acres of level and sloped areas have been direct-seeded at the Waite Amulet property. Another 50 acres were covered with overburden, as physical site conditions would not permit access of reclamation equipment; overburden was spread during the wintertime on frozen tailings.

Although studies showed that the No. 3 tailings could be satisfactorily amended with agricultural limestone, which was confirmed by subsequent field trials, equipment access problems were encountered due to poor drainage in the center of the tailings area.

Presently, low-lying areas are being raised by filling with non-sulphide gold tailings from current milling operations at Noranda-Horne. The gold tailings will then be directly seeded. Revegetation has formed part of a continuing water quality control program being undertaken by the Horne Division. A history of the reclamation program has been extensively described.[4]

Portions of the experimental and field programs have also been recorded on a film, available to the public, entitled, "To Make the Wasteland Green". Rio-Algom has completed revegatation of major portions of three inactive properties. The sections not completed are again characterized by impeded drainage. Since a program was implemented in 1970, extensive invasion by native shrubs and trees has occurred in forage seeded areas.

The phenomenon of native tree and shrub colonization of revegetated tailings has been recorded at numerous mines in eastern Canada. The exact role of birdsfoot trefoil in influencing colonization is not known, for unfortunately, there has been little documentation of such colonization. It is now being investigated by Rio-Algom.

The Long Term Approach

By initiating studies 2 years prior to mine closure, personnel at Selco Mining Corporation Ltd.'s South Bay mine were able to accurately assess reclamation procedures and costs and their relative importance in the overall mine closure program. Controlled environment studies provided a rapid indication that the use of agricultural limestone as a tailings amendment was not a practical method.

Extreme variation in amendment requirements was found between samples taken only a few feet apart. Consequently, a source of local overburden was evaluated and proven to be suitable for plant growth. The overburden was spread over frozen tailings in the winter of 1981-82, and seeded in May 1982. By some standards the work undertaken at South Bay could appear mundane. However, the approach taken enabled the company to make accurate planning schedules and costings with the confidence that tailings abandonment had been achieved in the most efficient manner possible.

Long term tailings reclamation planning is being emphasized at Noranda-Geco, Noranda-Brunswick Mining, and Site 6 and 8. At each, massive sulphide tailings with iron sulphide content, generally not less than 40 percent, occur. In the case of Noranda-Brunswick Mining, the iron sulphide content of the tailings is consistently in the 80 to 90 percent range.

Preliminary studies at Noranda-Geco have indicated that reclamation of the tailings dam embankment by direct seeding is a definite possibility. Controlled environment studies have shown that the agricultural limestone requirements are not excessively large, but that there is considerable variation in the limestone requirement along the face of the embankment, and that several problem areas could be present (see Figure 1). The extent of the variation still has to be fully determined before a practical field reclamation plan can be devised.

A serious atttempt is being made at Noranda-Brunswick Mining to devise methods for direct seeding of the very rich sulphide tailings. Sufficient overburden is simply not available to cover the estimated 3,000 acres of tailings that will be created by presently planned mining operations.

In addition to the tailings investigations, reclamation of all disturbed areas at the No. 6 pilot plant of the mine are being evaluated. Such areas include pyritic waste rock, water treatment sludge ponds, and sections from which all surface soils had been stripped.

At present studies have shown that such areas may be revegetated directly but field confirmation is required. Sites 6 and 8 present interesting contrasts, for they emphasize how misleading tailings characterization techniques can be.

Site 6 is particularly difficult, as it has not been possible to date to determine what would be suitable direct-seeding methods, even though initial tailings analyses using standard soil testing techniques do not indicate as severe a situation as has been encountered elsewhere.

By contrast, reclamation at Site 8, despite exceedingly acid conditions, would appear feasible from controlled environment studies. Again though, field confirmation trials are necessary.

Over the last 10 years reclamation of sulphide tailings in eastern Canada has made considerable progress. It is true to say that an understanding of the factors affecting plant growth on these types of tailings is very far from being understood in chemical and biological terms. From a management viewpoint, though, it has developed to the stage where costly and unsuccessful reclamation programs can be avoided.

Where large scale reclamation programs are or have been undertaken, they have been initiated with confidence that success will result considering that biological, not engineered, systems are being created. ■

THE ESTABLISHMENT OF VEGETATION ON HIGH IRON-SULPHUR MINE TAILINGS BY USE OF AN OVERBURDEN

R. E. Michelutti 1/

ABSTRACT

Since 1971 numerous tests have been conducted at Falconbridge Nickel Mines Limited to establish vegetation on tailings containing high percentages of pyrrhotite.

The object was to produce a self-sustaining vegetative cover which would reduce or eliminate seepage long after the operations cease. This solution was not a simple task, however, due to the low pH (3.0), the heavy metal toxicity and the hard pan produced by the pyrrhotite.

Vegetation research, mainly on Nickel Rim Mine tailings, led to the use of overburdens as the most promising method of achieving the primary objective of a maintenance-free vegetative cover. The ideal overburden was found to be three inches of coarse material (1/4 inch) overlain with three inches of loam. The coarse material prevents the upward leaching of solubilized metallic salts, while the loam provides a suitable growth media for the plants.

1/ Environmental Biologist, Falconbridge Nickel Mines Limited, Falconbridge, Ontario, P0M 1S0, Canada

Introduction

The sulphide ores of the Sudbury Basin contain economic quantities of nickel, copper and iron, which occur mainly in the minerals pentlandite, chalcopyrite and pyrrhotite respectively. These valuable minerals are associated with a variety of igneous silicate host rocks.

In order to separate the metallic minerals from the waste host rock, the ore must be crushed and ground to at least minus 65 mesh. Separation t is effected by the process of flotation and wet magnetic separation. O ton of average grade Sudbury ore, once processed, results in the followi products:

1. 250 lbs. of copper-nickel concentrate
2. 500 lbs. of pyrrhotite (iron-sulphide concentrate)
3. 900 lbs. of coarse tailings (+25 microns)
4. 350 lbs. of tailings slimes (-25 microns)

The tailings are classified by hydrocyclones to produce a coarse fractic (70%) called sands and a fine fraction (30%) called slimes. The coarse fraction is returned to the mine as backfill and the slimes are discarde with the pyrrhotite. Falconbridge Nickel Mines Limited mines four milli tons of ore annually which results in 1,800,000 tons of tailings slimes pyrrhotite, occupying a volume of 30 million cubic feet. This waste material is pumped as a slurry containing 15% solids, to landlocked basi or low lying areas called tailings ponds.

Here the solids are retained behind dams and the water is decanted off a treated prior to re-use or discard. Once these tailings ponds are full, however, they must be reclaimed, to eliminate or reduce pollution arisir from them, as well as to improve the aesthetics of the area.

RECLAMATION PROBLEMS

The most acceptable method to date in reclaiming these tailings areas is by means of a vegetative cover. This, however, is no simple task for the following reasons:

1. The tailings acidify with time to pH 2.5 - 3.0
2. Heavy metal concentrations are high, especially upon acidification
3. The top 2 inches to 2 feet becomes rock hard due to a complex iron-sulphur matrix called a ferruginous cap
4. The tailings are devoid of nutrients and appropriate bacteria

EXPERIMENTAL WORK

(a) Fertilizers

Experiments were conducted in the laboratory and field with the objecti of establishing a maintenance free vegetative cover that would revert back to nature. Of the fertilizers tested, 6-9-6 with 50% urea formal

allows the nitrogen to be released slowly and should therefore reduce or eliminate maintenance.

(b) Neutralizing Agents

From the laboratory tests, the minimum amount of limestone required to sustain plant growth over the 3-month test period was 10 tons per acre. The limestone used was "Beachville feed-grade" which has a 70% coarse fraction (sand particle size) and 30% fine fraction (dust size). This was chosen over other neutralizing materials for its ease of handling as well as for the coarse fraction which would act like a buffer and maintain a constant pH. In the field tests, however, the test plots acidified in 2-3 months' time to pH values ranging from 3.5 to 4.5. This was believed to be caused by the upward movement of sulphuric acid by capillary action during hot dry periods. The acid would also dissolve metallic salts and concentrate them upon evaporation on the surface. This was evidenced by white and yellow crystals (mainly Ca and Mg sulphates) on the surface of our tailings. It soon became apparent that continued maintenance would be necessary to maintain a vegetative cover on our tailings area.

(c) Overburdens

Due to the initial difficulties encountered with direct seeding in the tailings, tests with overburdens were begun in the laboratory and field. The overburdens used, ranging from gravel to black loam, had a pronounced effect in increasing yields, as well as allowing legumes to become established for the first time. Of the soils tested, black loam resulted in the greatest yields in the 3-4 month test period. However, there was some concern as to the long term effects. Due to the fine particle nature of the black loam it was felt that the upward movement of solubilized metallic salts would not be halted by the black loam and that after several years the concentrations would become toxic.

Dr. G. Courtin of Laurentian University was consulted and a decision was made to conduct research toward a master's thesis on this problem with Falconbridge Nickel Mines Limited personnel assisting with materials, assays and labour. Tony Spires, who was performing this work, came up with some basic conclusions. First of all, the black loam did result in the best initial growth of plants, but also had the highest heavy metal accumulation at the end of the experiment. The coarse sand and gravel overburden on the other hand acquired very little if any metallic salts, but growth was mediocre due to lack of moisture. The ideal overburden in these tests was a 3-inch layer of 1/4 inch crushed slag overlain with 3 inches of black loam. The slag broke up the capillary action and the black loam provided a growth medium with a good cation exchange capacity (128.5 me/100g) and moisture retention capability (137g/100g).

As with some of our earlier experiments, Mr. Spires demonstrated that a solid barrier between the tailings and 6-inch overburden resulted in zero to poor growth due to a lack of moisture.

REVEGETATION PROJECTS

(a) Nickel Rim Mine

Nickel Rim Mine is an abandoned mine which was purchased by Falconbridge Nickel Mines Limited in 1964. With the purchase of this property, Falconbridge then became responsible for the pollution originating from the tailings area, covering approximately 30 acres. These tailings are composed predominantly of siliceous gangue (66%) and pyrrhotite (34%) and had been exposed since 1958.

After several tests with various overburdens, the results were sufficiently successful that we proceeded to reclaim 20 acres by use of an overburden. The overburden material used was a sandy loam located within one mile of the site. The cost of this project is outlined below.

Materials	Cost/Acre
Limestone	$180.00
Fertilizer	160.00
Seeds	90.00
6-inch Overburden (includes Labour)	660.00
Labour (liming, fertilizing and seeding)	100.00
Total	$1,190.00

A test plot with similar overburden material has been monitored since 1973 for pH to determine if re-acidification is taking place. The initial pH in September 1973 was 7.4 and as of March 1975 was 6.6. No maintenance on the 20-acre area has been conducted since it was established in 1975.

(b) Hardy Pyrrhotite Stockpile

In the Onaping area, 30 miles northwest of Sudbury, pyrrhotite had been stockpiled for future reclamation and recovery of values. This resulted in severe reclamation problems since the pyrrhotite containing 56% iron and 36.5% sulphur had not been diluted with tailings (siliceous gangue) as in other areas.

Adjacent to the pyrrhotite stockpile, a sandy gravel overburden was being removed from an open pit operation. This material appeared suitable as overburden and a 6 foot deep cover was placed over the pyrrhotite stockpile at no cost to the reclamation project, due to the close proximity of the pit operation.

This 17-acre area was seeded with the use of conventional farm equipment at a cost of $326.00 per acre in August 1973. There was some concern, however, that the sand-gravel overburden was so coarse that the nutrients would wash out faster than in a loamy sand overburden. To maintain a healthy vegetative stand an additional 300 pounds per acre of 12-18-12 40% sulphur coated urea fertilizer was applied during August of 1976 at a cost of $150.00 per acre.

The vegetation is doing very well and numerous unidentified weeds as well as several tree species, including trembling aspen and birch, have already encroached.

(c) East Mine Tailings

The East Mine tailings should have been relatively easy to vegetate since pyrrhotite was not discharged in to this area. These tailings were seeded in 1969 without the use of any overburden and the resulting grass cover was poor. Large bare areas were scattered throughout, without any vegetation whatsoever. It soon became apparent that the tailings were not homogeneous and that these bare areas had a very high iron content and a pH of 2.5. Unknown to the reclamation group at that time was that high iron waste products had been dumped into this area. These bare patches were covered with gravel at a cost of $404.00 per acre and re-seeded.

The vegetation cover initially was not very healthy and required annual maintenance for the first five years. This was possibly due to the proximity of the nearby smelter.

More recently, however, birdsfoot trefoil and alfalfa have begun to spread. Fertilizer requirements should be reduced since these legumes can produce their own nitrogen.

OBSERVATIONS

1. Tailings should be pumped over pyrrhotite stockpiles during the final stages of a tailings pond to eliminate the need for an overburden.

2. The use of domestic garbage, mine wastes, etc. as overburden materials should be investigated. This would result in one revegetation scheme for both the tailings and garbage.

3. Planning in conjunction with operating departments will save considerable dollars, e.g.- removal of overburden materials from open pits or dam construction, etc.

4. Finally, it should be kept in mind that continued monitoring of the vegetation is essential in order to determine the effectiveness of the overburden material in achieving a maintenance free vegetation cover.

CONCLUSIONS

Based on past and continuing research on tailing pond reclamation at Falconbridge Nickel Mines Limited since 1971, the following conclusions are reached:

1. Tailings areas containing high quantities of iron-sulphur and/or heavy metals can be vegetated successfully by use of an overburden material.

Conclusions (cont'd)

2. The ideal overburden should be coarse enough to reduce or eliminate upward leachate migration from the tailings while at the same time providing sufficient moisture retention and a cation exchange base for the vegetation.

3. Initial establishment costs by using overburdens are quite high but maintenance work is substantially reduced.

Lysimeter investigations on uranium tailings at CANMET

G.M. RITCEY and M. SILVER
Extractive Metallurgy Laboratory
Mineral Sciences Laboratories, CANMET
Energy, Mines and Resources Canada
Ottawa

ABSTRACT

The processing of uranium ores produces tailings that could constitute environmental problems. At most operations the tailings are dumped into a designated area, with the ultimate acid drainage occurring if sulphides are present, together with the release of metal constituents to the rivers and streams. If the chemical reactions occurring within the tailings could be predicted, perhaps methods could be developed to either increase or decrease the rates of reaction. One such study has been in progress at CANMET during the past three years. The paper describes the use of lysimeters containing low-grade and complex uranium tailings to determine the effects and interactions of bacteria, sulphides and solvent extraction organics on the release of radionuclides and on acid production. A simulated rain cycle nine-fold the normal was used and the lysimeters were subjected to timed intervals of light and darkness. As a result, the tests simulated a 25-year period.

Introduction

Although Canadians derive major benefits from uranium, there are environmental and health consequences, not yet fully understood, from the associated mining and milling operations. A major project at CANMET (Canada Centre for Mineral and Energy Technology) has the ultimate goal of ensuring that any adverse effects on man and environment, now or in the future, resulting from the processing of uranium should be acceptably low. The magnitude of the task was exacerbated by the fact that the increased demand for electrical energy and the resultant increased prices for uranium oxide during the 1970s led to a rapid expansion in the industry. Annual world demand for uranium was expected to increase 12-15 fold in the next quarter century, with annual requirements of between 200,000 and 300,000 metric tonnes anticipated by the year 2000[1]. Currently, the demand is low and the prices for the oxide have decreased.

The major problems stem from the discarded materials, "tailings", which contain radioactive substances and other contaminants. Most of the existing uranium mills operate with an efficiency of greater than 90% uranium extraction. Any uranium not solubilized in the leaching process will be discharged to the tailings and will thus constitute a source for daughter products. Uranium tailings, resulting from sulphuric acid or sodium carbonate leaching processes, contain (after uranium recovery) much of the initial radioactivity of the original ore before processing. A uranium ore containing 0.1% uranium will contain 330 pCi Ra^{226}/g ore. Therefore processing of 1 million tonnes of such material will result in 0.33 kg Ra^{226}. Other long-lived radionuclides in equilibrium with the ore would be Th^{230} at 15.4 kg and Pb^{210} at 3.5×10^{-5} kg per million tonnes. Much of the tailings in Canada (Elliot Lake) are made up of quartz, pyrite and calcium sulphate (resulting from lime neutralization at discharge), metal hydroxides, and precipitated thorium and rare earths. Solu-

G.M. Ritcey

G.M. Ritcey is head of the Process Metallurgy Section, CANMET, Energy Mines and Resources Canada, Ottawa. He received his B.Sc. in chemistry at Dalhousie University and joined Elorado Nuclear Limited in 1952, where he spent the next 15 years successively as chief chemist at Port Radium, N.W.T., and later chief chemist and head chemical research, at the R&D Laboratory, Ottawa. He has wide experience in various phases of hydrometallurgy, and has been involved in the research and development of processes from the bench to the plant scale. Major R&D projects have included cobalt, nickel, copper, uranium, thorium, rare earths and vanadium. Mr. Ritcey has authored or co-authored over 60 technical papers, and 10 patents have been issued on various metal recovery processes. He is the co-author of a textbook on solvent extraction and is editor of the *Journal of Hydrometallurgy*.

M. Silver

Marvin Silver graduated from the University of Manitoba with a B.Sc. (1963) and an M.Sc. (1966) in microbiology. After obtaining his Ph.D. (1968) in microbiology from Syracuse University and a post-doctoral year at Indiana University, he was on faculty at Laval University for nine years. Most of his research work has been on the biology of the iron-oxidizing thiobacilli, and on the use of these bacteria for the recovery of copper and uranium. Since joining CANMET in 1978, he has been involved with research on the environmental aspects of base metal and uranium mining.

Keywords: Mineral processing, Lysimeters, Tailings, Uranium tailings, Environmental control, Elliot Lake, Rabbit Lake, Midwest Lake, Key Lake, Radionuclides.

tions accompanying these solids contain calcium sulphate, radium, ammonia and nitrate. Fresh tailings areas have a pH of 6.5-9.0, whereas seepage and runoff from abandoned tailings have a pH of 2-3.

Impoundment areas for tailings range in Canada from 35 to 400 acres. It is estimated that uranium tailings from previous operations in Canada amount to 100 x 10^6 tonnes covering more than 1000 acres[2]. In the U.S.A., in the Colorado River basin alone, more than 12 x 10^6 tonnes of tailings containing about 8000 curies of radium exist at abandoned mill sites[3]. Thus, with increased mining and processing of the existing uranium reserves, the environmental consequences of the disposal of such tailings wastes will increase considerably.

When uranium milling started in Ontario in the mid 1950s, tailings "disposal" areas were designed according to the best available technology and the methods used were acceptable to the federal and provincial regulatory agencies. Tailings, after neutralization to pH 8 with lime, were deposited in small lakes and swampy areas and gravel or mine-waste rock dams were used to contain the tailings within these areas. No particular problems were expected from the uranium-mill tailings areas. The tailings basin provided a settling area for the solids and the clear effuent flowed through the overflow decant for discharge into the receiving watercourse. Such ponds of radium-bearing mill tailings, typically containing 400 or more picocuries of radium per gram of solids, become repositories for large quantities of radium during the active mill operation. Abandoned tailings dams, unless maintained, may break and release tailings containing radionuclides to the streams where radium dissolves and contaminates the watercourse. Also, as the inactive tailings pond dries, radium-bearing dust is scattered locally by the winds[4,5].

After a few years of operation, it was found that the effluents and seepage from the tailings areas were becoming more acid and that the radium levels were increasing[6]. The acidity was caused by chemical and bacteriological oxidation of pyrite, which constitutes 5 to 8% of the tailings. Chemical oxidation would lower the pH to about 4, and bacterial action would then lower it to 2 or less.

In Canada, barium chloride was introduced in 1964 to precipitate radium as an insoluble barium-radium sulphate and has been effective in removing over 99% of the dissolved radium in the effluents from the active tailings areas. The addition of 0.07 to 0.11 lb of barium chloride per 1000 gal of discharge or seepage effluent from inactive and active tailings areas produces a barium-radium sulphate coprecipitate which settles out in a subsequent settling pond to give much reduced concentrations of dissolved radium. Typical values of 12 and 1000 pCi/L in the seepage and effluent are reduced to between 3 and 10 pCi/L in the settling-pond discharge. These can be compared with a federal limit of 10[7] and current Ontario and Saskatchewan objectives of 3 pCi/L of dissolved radium[8].

The present $BaCl_2$ treatment, although effective in significantly lowering radium seepage, produces a barium-radium sulphate precipitate which could eventually break down by bacterial action and thus release radium and barium compounds into the environment[9]. Thus, unless technology is developed for eliminating radium from the tailings, control must be maintained long after the mill ceases operation.

Recognizing this need for new technology, and aware that there is a lack of definitive data for correlation and prediction of the chemical occurrences in tailings as the tailings become weathered, CANMET began several years ago to determine the many factors affecting the environment due to uranium tailings. In addition to work on the tailings, research included the development of new alternative processing technology which is chloride-based to solubilize the radionuclides for subsequent isolation in the mill. The work includes the hydrogeologic examination of present tailings and old tailings impoundment areas by drilling, the characterization of seepage plumes, the production of compost from municipal wastes for tailings cover and the development of vegetation technology for those areas[3,6,10]. Laboratory studies of tailings, using various types of lysimeters, are being compared with on-site hydrogeochemical measurements to determine if a relation exists between the laboratory and the field results and if chemical and physical predictions of occurrences in the abandoned and current tailings based on laboratory studies are valid.

The word lysimeter is used frequently throughout the text, and the following is a composite definition[11, 12]: "a structure containing a mass of soil, and so designed as to permit the measurements of water draining through the soil. It consists of a basin, having closed sides and a bottom fitted with a drain. Quantities of material and/or artificial precipitation are measured, the deep percolate is measured and analyzed, water of evaporation is measured, water taken up to plants is weighed, etc."

This paper describes the results that have been obtained in continuing laboratory tailings studies[13] in various sizes of lysimeters and the comparisons with actual tailings areas. Simulated weathering-time cycles are described and correlations are made with measurements on actual tailings. The interaction of bacteria and organics on the oxidation of sulphides to sulphuric acid are studied, as well as the release of constituents such as Ra^{226}, $SO_4^{=}$, total iron, uranium and the effect on pH of the effluent. Because a study of tailings weathering is a long-term process, 9 times the normal rain cycle was arbitrarily used to determine solubility effects in a simulated 25-year period, in order to compare with old abandoned tailings that were laid down for about 25 years. Thus, it might be possible to predict i) the production of acid and the solubilization of metallic elements by the action of iron-oxidizing bacteria; ii) the effects of organic solvent extraction reagents (used in the uranium purification process) on these bacteria; and iii) the leaching of radium-226 and other chemical constituents caused by water percolation through a tailings area. The release of arsenic and nickel are also followed in studies on complex uranium tailings.

Previous work at CANMET had shown that there was a certain degree of toxicity to bacteria due to organic solvent extraction reagents[14]. These reagents were incorporated into the

tests to determine whether there was sufficient quantity present to decrease the oxidizing effect of bacteria on sulphides.

Procedure and Experimental

Table 1 shows the chemical analyses of the tailings used in the various lysimeter tests. These samples were obtained from a conventional low-grade operation at Elliot Lake in Ontario and the Rabbit Lake operation in Saskatchewan. In addition, small-scale tests were performed on tailings resulting from the leaching of the complex high-grade uranium areas of Key Lake and Midwest Lake in Saskatchewan, which also contain appreciable arsenic and nickel. Because of initial blending with lower-grade material of those two ores before leaching, the Ra^{226} content is not perhaps as high as might be anticipated. The latter two properties are not yet in operation.

Early in 1978, three reinforced plexiglass lysimeter boxes (Fig. 1) with approximate dimensions of 120 cm by 55 cm by 120 cm (length, width and height) were constructed and loaded to a depth of approximately 60 cm with fresh solid uranium mine-mill waste. The tailings were obtained by decantation of the tailing neutralization discharge from the uranium milling circuit of the Rio Algom Quirke Mine at Elliot Lake, Ontario, immediately after addition of lime. A portion of the finer tailings was lost during this procedure and is the reason for the relatively low radium-226 content. This material contains, on a dry weight basis, 2.5-3.5% pyrite, 0.72% sulphate (as sulphur), 2.82% total iron, 0.007% uranium, 0.025% thorium and 170 pCi/g radium-226. The contents of each lysimeter box are described in Table 2.

The lysimeter boxes were designated 'A', 'B' and 'C' and each was loaded with approximately 1 tonne of tailings. To lysimeter box 'A', 175 L of water containing 90 mL/L of kerosene (Shell 140), 5 gm/L of Alamine 336 and 5 mL/L of isodecanol was added. After equilibration for 2 days, box 'A' was flushed with 175 L of water and inoculated with a washed 72-hour culture of iron-oxidizing thiobacilli isolated at Elliot Lake. Boxes 'B' and 'C' were flushed with 175 L of water, and box 'B' was inoculated similarly. The water level in the lysimeter boxes was maintained within 10 cm of the surface by a syphon tube from the effluent port, allowing water saturation and thus anaerobic conditions to exist below this level. Modified simulated conditions were automatically controlled with exposure to infra-red and ultra-violet lamps and a fan which were activated every 1½ hours, and 5.2 L of water which was sprayed on each box every 8 hours, resulting in an application rate 9 times the average annual precipitation of the Elliot Lake area (996.1 mm). Thus, if the leaching rate of the chemical constituents were dependent only upon the water applied to the tailings, a chronological acceleration of nine-fold should be achieved, and 40 days of experimental time would be equivalent to 1 simulated year as far as water application was concerned. Bacterial oxidation of pyrite would also be accelerated because of the higher average temperature and increased availability of water and oxygen. The water supplied to box 'C' contained 1-3 mL/L of hypochlorite solution (Javex bleach) containing 5% available chlorine to inhibit bacterial action, and thus sulphate generation, while maintaining oxidizing conditions. The experiment was conducted at ambient temperature (18 ± 4°C), with extraneous light being excluded by black curtains. The water level in the lysimeter boxes was maintained within 10 cm (or less) of the tailings surface by a syphon tube from the effluent port. Liquid samples, taken from the effluent ports at intervals of approximately 2 weeks, were analyzed for total iron, pH, sulphate, uranium, thorium and radium-226. The effluent and core samples taken from the centre and each corner of lysimeter box 'A' were periodically analyzed by gas-liquid chromatography for kerosene. Due to interference of the kerosene on the chromatographic spectrum of isodecanol, this latter compound could only be detected, but not quantified. Alamine 336 was analyzed by a colorimetric procedure[13]. Subsequently, a method has been developed at CANMET for kerosene using gas chromatography.

Note that all results are reported on the simulated time basis of 1 experimental year = 9 years of water application with a time cycle of light and darkness and drying. No freezing or thawing tests were carried out to complete a true weathering cycle.

Results and Discussion

Lysimeter Boxes

Figure 2 shows the pH and concentrations of radium-226, sulphate and total iron in the effluents of the three lysimeter boxes over a period of about 900 days, simulating about 22½ years during which time 13.8 tonnes of water were applied. No

correction to these results is applied to compensate for evaporation of 9.3 ± 2.3%. The total amount and proportion of each constituent initially present in each of these three lysimeter boxes removed during the course of this experiment are summarized in Table 3.

Radium-226 is constantly being solubilized, the concentrations in the effluents from lysimeter boxes 'A' and 'B' being between 100 and 300 pCi/L for about the first 7.5 simulated years, increasing thereafter and remaining around 500 pCi/L. To demonstrate the effect of bacterial action on the tailings, box 'B' was flooded for a 200-day period after 17.5 simulated years, thus depriving the bacteria of one of their metabolic necessities, oxygen. The inhibition of the bacteria resulted in increases in pH and radium-226 concentration and decreases in total iron and sulphate sulphur concentrations in the effluents of box 'B' in comparison to box 'A', which was not flooded. The radium-226 content of the effluent of lysimeter box 'C' is between 85 and 240 pCi/L for the first 7.5 simulated years and increases thereafter to between 1000 and 2000 pCi/L. The decrease in the concentration of sulphate in the pore water would increase the solubility and thus mobilize the radium-226. The amounts and proportions of the radium-226 eluted from lysimeter boxes 'A', 'B' and 'C' are 5.77 μCi and 2.96%, 5.70 μCi and 3.20%, and 9.39 μCi and 5.86%, respectively.

Initially, the concentrations of sulphate and total iron of the effluents from each of the three lysimeters are similar. Subsequently, the concentrations of both sulphate and total iron in the effluents increase similarly in boxes 'A' and 'B', with the pH decrease correlating to the cumulative sulphate removal. The concentrations of these components are much less in the effluents of box 'C'. The total iron consists of both ferrous and ferric species; the ferric iron results from bacterial oxidation of pyrite and ferrous iron, whereas the ferrous iron results from the action of ferric iron and pyrite under the reduced conditions below the water table[16]. Sulphate is generated not only by the dissolution of gypsum, but also by bacterial oxidation of sulphide minerals, bacterial oxidation of elemental sulphur arising from the oxidation of sulphide minerals by ferric iron and the formation of secondary ferric iron minerals[16]. Thus, the presence of elevated concentrations of iron and sulphate in the tailings effluents is an indication of bacterial activity. The lower total iron to sulphate molar ratio of the effluents from box 'C' indicates less metabolic activity of the iron-oxidizing bacteria due to the presence of the bacteriostatic agent (NaOCl). This ratio also decreases during the course of the experiment[13] due to the incomplete bacterial and chemical oxidation of pyrite, which would occur according to the equation

$$2FeS_2 + 7O_2 + 2CaCO_3 + 2H_2O \rightarrow 2FeSO_4 + 2CaSO_4 \cdot 2H_2O + 2CO_2$$

yielding a theoretical iron to sulphate molar ratio of 1:1. In reality, this ratio would be greater than 1:1 due to the solubility of gypsum and the oxidation of other sulphide minerals in the tailings.

Thorium was not extracted from the tailings contained in any of the lysimeters, the concentrations in the effluents being consistently less than 0.1 mg/L. After an initial release, uranium was not found in the effluents of lysimeters 'A' and 'B' until after 7.5 simulated years and from lysimeter 'C' not until after 17.5 simulated years. Until 20 simulated years, when uranium was detected in the effluents, it was rarely found in concentrations greater than 1 mg/L. After 20 simulated years, the uranium concentration in the effluents of box 'A' increases to approximately 10 mg/L. In the effluents of box 'B', which was flooded between 17.5 and 22.5 simulated years, and of box 'C', which was treated with bleach, the uranium concentrations were always less than 1 mg/L.

The mixture of organic compounds originally introduced into lysimeter box 'A' was almost completely eliminated, either by voidage through the effluent or by evaporation within the first 11 simulated years. Kerosene, the largest component in the mixture of organic compounds, was quickly eliminated from the tailings, its concentration in the tailings decreasing almost by 80% in the first 4 simulated years and by more than 95% in the first 10.8 simulated years. Examination of the core samples from the centre and at the corners of lysimeter box 'A' indicated migration of the kerosene toward the effluent outlet. Isodecanol, which could be detected but not quantified due to the interference of the chromatographic spectrum by kerosene, was always found with the kerosene. The elution of Alamine 336 was observed to be much more rapid and was undetected after a 2-year simulation period.

Periodically, throughout the evaluation period, the boxes were photographed in order to compare the iron layering due to jarosite formation. There was a significant amount produced after 4 months of operation (approximately 3 years simulation) and acid production in the tailings was also noted. The presence of bacteria increased the acidity and dissolution of iron, but inhibited Ra^{226} release. Subsequently, the hydrolysis of iron would result in acid conditions. Continual application of water solubilized Ra^{226}.

Core sample profile analyses of the lysimeter contents for radium, sulphate and iron are shown in Figure 3 after a simulated 20-year period. The radium is being leached from the top layers downward, with no change or even enrichment of this radionuclide occurring toward the bottom of the lysimeter. Similar trends, but less pronounced, are shown for iron and sulphate. (The hash marks in Fig. 3 indicate a range of analysis.) The downward movement of these constituents is similar to some, but not all, sites of the Nordic tailings area at Elliot Lake[6].

A calculation, based on the rates of radium release over the simulated 25-year period, indicates that radium will pass through the tailings contained in the lysimeter boxes in about 300 simulated years. However, such calculations should not be directly extrapolated to actual tailings sites without obtaining specific site data.

Comparison of Lysimeter Size for Reliability

Concurrent with the studies on the large lysimeters, other measurements have been taken on various sizes of tailings tests to determine whether quick, small-scale tests could be useful

FIGURE 3A. Core sample profiles of lysimeter box—Fe and S.

FIGURE 3B. Core sample profile of lysimeter box—Ra^{226}.

FIGURE 4. Comparison of lysimeter size based on volume of water applied per kg mass of tailings (Elliot Lake).

FIGURE 5. Effect of volume of water applied per kg mass of tailings (Rabbit Lake).

for predicting radium release. In these tests, two sizes of glass columns and shake flasks were used, and the data derived were compared to the box lysimeters, based on the amount of water applied per kg of tailings.

The small columns were 5.6 cm diameter by 25 cm long and filled with 0.75-kg tails. The large columns were 9.8 cm diameter by 90 cm long and filled with 12.5-kg tails. The water percolation rate was 200 mL weekly for the small columns and 1.75 L weekly for the large columns. The shake flask tests consisted of a 25-g quantity of the tails together with 250 mL H_2O at 30°C in a flask being agitated on a mechanical gyratory shaker. Each week the water was separated and analyzed; fresh water was then added to the solids and the shaking was continued. The results of these tests are given in Figure 4, based on the volume of water applied per kg mass of tailings. Lysimeter size does not seem to be important and the radium in the effluent appears to be related to its aqueous solubility. The results for the shake flasks and lysimeter boxes are similar due to the presence of bacteria. The column tests were similar to one another, but there were no bacteria in the columns. Note the difference in the two types of base present in the small columns. With a quartz base, the elution of radium is greater compared to the column with a limestone base. The presence of the limestone results in the radium being removed from solution by precipitation probably as the carbonate, thus resulting in a decrease in the concentration and the release of this radionuclide in the column effluent. A similar decrease in the concentration of radium occurs when a peat moss base is used.

Saskatchewan Ores

The work described above was on the Elliot Lake tailings. A comparison of the results obtained from tailings from H_2SO_4 leaching with or without chlorate as oxidant of the Rabbit Lake ore is shown in Figure 5. The concentrations of radium-226 in the leaching media from the shake flask and column tests on the tailings of the ore that had been leached with

FIGURE 6. Effect of volume of water applied per kg mass of tailings (Midwest Lake and Key Lake).

FIGURE 7. Arsenic and nickel solubilization by water from Midwest Lake tails.

sulphate in the presence of chlorate are in reasonably close agreement. However, radium is released more readily from the tailings of the ore that had been leached with sulphate in the absence of oxidant (about 1500 pCi/L) than that which had been leached in the presence of chlorate, indicating that the treatment of the original ore could be a critical factor in determining the solubilization characteristics of this radionuclide.

The high-grade complex uranium ores of Key Lake and Midwest Lake, containing nickel and arsenic, were similarly examined and these results are given in Figure 6. Because neither company has a mill yet in operation, the tailings were obtained from uranium extraction experiments. These high-grade ores, depending on the original blend of ores in the leach, will result in a difference in the radium content in the tails. A level of about 6000 pCi Ra^{226}/g would probably be expected for tails from such ore. In the tests shown, the levels range considerably lower because of the original blend. Nevertheless, there appears to be reasonable agreement of radium leaching patterns with the shake flask tests and the small column lysimeters for the Midwest tests when sufficient water is applied. The Key Lake data did not show such close agreement. Figure 7 shows that there is very little dissolution of nickel, but that there is a significant and continuous dissolution of arsenic with continued application of water of 0.01-0.04 g/L.

Shake flask tests on the Midwest tails were carried out to determine the effect of bacteria on release of constituents. These results (Fig. 8 and 9) indicate that in the presence of bacteria there is an increased acidity and therefore increased uranium solubility. There is also an initial increase in the solubility of nickel and iron. The presence of bacteria slowed the arsenic and radium dissolution rate. By the 7th week all the bacteria had died, due possibly to the arsenic and/or free acid concentrations.

Lysimeter Test Pit System

During the small-scale lysimeter test program, large-scale lysimeter tests were conducted for 5 years at the Rio Algom Quirke Mine, Elliot Lake[10]. The purpose of the large installation was to evaluate the effect of the different surface treatments of tailings on the oxidation of the sulphides and on the quality and quantity of the effluent. The initial tests indicated discrepancies between the amount of rainfall measured and the amount measured in the underflow from the pits. Subsequent tests in the laboratory were carried out to determine the various parameters affecting drainage, evaporation and transpiration, and the measurements were compared to measurements in the pits[17]. The test pits were 30 by 30 by 5 ft deep (with sides sloped at 45°), containing a single 10-cm-diameter drainage pipe. (If subsequent pits were to be constructed, the authors recommended a 3-pipe drainage system.) The tests were conducted in pits, each containing approximately 200 tonnes of tailings. Wood chips, gravel and also vegetation (grasses) were used as cover. The hydrology was studied by measuring density, porosity, water permeability, water retention, storage capacity of the wood chips and air migration through the wood chip cover, and capillary action. It was recognized that the shallow pit could not duplicate the effect of the capillary forces acting on an actual tailings pond.

The effect of climate on the pits, with extremes of cold winters and dry summers, created cracks in the tailings. Because of the scale of the experiment, difficulties were encountered in the control of the percolation and the maintenance of a water table. Some of the drainage tiles became obstructed by chemical precipitates, and some of the effluents were modified by the active iron-oxidizing bacteria during the sampling procedure.

The test pit measurements indicated that none of the treatments prevented pyrite oxidation and that it took 2.5 years for signs of oxidation (acidic effluents) to occur[10]. The behaviour of the lysimeter pit system was evaluated and no explanation for its behaviour could be given. It appeared that control of an experiment of this size exposed to natural conditions is extremely difficult.

In order to solve the problem, simple lysimeter models were recommended for study, measuring the following parameters:[17]

porosity	storage capacity
permeability	distribution of water
water saturation	penetration depth of rainfall
retention capacity	relationship between rain intensity and underflow

Pore Water Measurements

External contract studies were conducted on the chemical composition and movement of pore water in inactive tailings (Nordic) in the Elliot Lake district during 1979-1980[17]. These inactive tailings, 20-25 years old, had been vegetated.

FIGURE 8. Effect of bacteria on pH and release of Ra^{226} and U from Midwest Lake tails.

FIGURE 9. Effect of bacteria on release of Ni, As and Fe from Midwest tails.

Piezometer tests have indicated acidic water occurring in these vegetated areas due to the oxidation of pyrite (pH 3-7). The plume measurements indicated sulphate in the seepage water extending greater than 300 metres from the dam compared to only 15 metres for the radium. That is, the radium appears to be sorbed and desorbed, by an ion exchange mechanism, or by precipitation followed by solubilization, thus slowing its movement through the tailings. There is a continual build-up of organic soil in the uppermost layers, and together with the depletion of pyrite there is a possibility that the acid generation will decrease with time.

Future Considerations

Although we intend to continue the on-going large lysimeter tests for a prolonged period to obtain additional data, other lysimeter tests should be carried out.

Tests are in the initial stages on a new set of lysimeter experiments to further the knowledge already obtained. In the four test boxes recently started, we are studying the relationship between a compost or fertilizer cover together with vegetation on the seepage efforts, with and without the presence of bacteria. The presence of the humus-compost material (made from municipal garbage, as part of CANMET's tailings program) may result in a decrease in oxidation of the pyrite and therefore a decrease in rate of generation of acid and an increase in the release of radionuclides. Subsequent tests will include the results of chemically fixing the tailings as well as radionuclide sorption from the seepage effluent.

In addition to the lysimeter tests in progress and those planned for the future—all tests primarily to obtain a better understanding as to tailings predictability—work at CANMET will continue on removal of radionuclides from the ores prior to leaching by high-intensity magnetic separation and flotation. Preliminary work on salt washing of the tails to remove radium[13,18] should be pursued. With that in mind, we have recently installed a lysimeter box under test to determine whether the rate of radionuclides leaching can be significantly accelerated by a brine percolation leach so that long-term disposal problems of continued maintenance can be minimized. Because all previous reported work has been on a laboratory scale, a larger-scale test in the lysimeter boxes could be more meaningful. Also, the brine solution would be collected for radium removal and isolation.

Conclusions

1. With respect to the large lysimeter boxes, the following can be concluded:

(a) The presence of organic solvent extraction reagents (kerosene, isodecanol and Alamine 336) has little effect on the solubilization of Fe, SO_4, Th and Ra from fresh tailings in the presence of bacteria. The Alamine is voided during the first 2-3 simulated years and the kerosene during the first 11 simulated years.

(b) In the absence of bacteria, the concentration of Fe, SO_4 and Th decreased and less acid generation was noted. Also, the $Fe_{sol}/SO_4^{=}$ ratio is greatly decreased and the rate of radium release was increased.

(c) Bacterial action increases the dissolution rate of uranium and the $SO_4^{=}$ generated by the bacteria appears to limit the solubility of radium.

(d) With the continued application of water, and the removal of $SO_4^{=}$, the radium is rendered mobile and is solubilized.

(e) Assuming a steady state of 500 pCi/L Ra^{226} in the effluent from the lysimeter, and that all the radium present in the tailings is leachable, removal of radium-226 from the tailings in the lysimeter would be complete in about 300 simulated years. Actual tailings piles would require extensive tests at depth to verify such a calculation.

2. Small-scale lysimeter and shake flask tests agree with the large lysimeter test with respect to radium release and water application rate.

3. Much of the data that have been obtained on the large lysimeter boxes have been substantiated in field tests on existing tailings dams with respect to the movement of tailings constituents. The migration of radium in the lysimeter boxes is downward.

4. Comparison of the lysimeter tests with large test pits showed that the rate of acid production was similar in both, occurring after approximately 3 years.

5. In the complex tailings, arsenic continues to be solubilized with the continued application of water.

6. Radium is removed more rapidly by water percolation from tailings that had been leached with H_2SO_4 in the absence of oxidant than from those which had been leached with H_2SO_4 in the presence of chlorate.

The major function of a lysimeter test unit is to provide for controlled physical conditions during a predetermined testing period. Therefore, the design of the lysimeter and its operation are of importance if the data derived from the tests are to be meaningful. The data should then be useful in predicting chemical reaction and mobility throughout abandoned and new tailings areas.

The tests to date at CANMET have proved to be useful and give us sufficient assurance to continue further testing. Shake flask tests represent a quick, easy test and columns also prove useful. More reliable data on permeability and other parameters, and on the effects of different surface treatments, can be achieved using the larger lysimeter under controlled conditions.

LEAK DETECTION IN IMPOUNDMENTS

Leaks can be detected by monitor wells as discussed in Chapter 60. An innovative new method for early warning of leaks is described by BOND and ROUSE (1985) whose paper is inserted in Chapter 60. They describe the use of Lysimeters placed beneath the tailings impoundment.

A useful geophysical technique employing remote sensing to locate leaks in water impoundments has been described by ARTHUR LANGE (1984) of Albireo Corp., Wheat Ridge, Colorado, whose paper is inserted in Chapter 59 on water impoundments and evaporation ponds. Since then, he has developed further innovations in this field which appear even more useful.

Two further review papers on the subject by WALLER and DAVIS (1984) and DAVIS, et al. (1984) are inserted below as additional sources of information.

It is important to realize, however, that repairing leaks in tailings ponds may not be an easy matter. The leaks are likely to be located under millions of tons of tailings material, and retrofitting a lining is unlikely to be possible. Grout curtains and seepage interceptor trenches may prove partly effective with treatment or return of the collected solutions--both relatively expensive. Leak detection may provide a way of identifying where to place the grout curtain or the seepage interceptor trenches.

At Quivira Mining Company's Ambrosia Lake operations, evaporation pond lings were not feasible at ponds adjacent to an acid tailings dam because reaction with carbonate rocks caused so much CO_2 to evolve. Could this possibly lead to a means of detecting leaks and migration of acid seepage by perhaps monitoring for CO_2 content of soil gas in surface soils or shallow boreholes around the tailings site?

Project Summary

Assessment of Innovative Techniques to Detect Waste Impoundment Liner Failures

M. J. Waller and J. L. Davis

Recommendations were developed for monitoring systems that will detect leaks in both new and existing landfill liner systems. Both solid and liquid impoundment sites were considered, but liquid waste impoundments were emphasized. The study was conducted in two phases. First a literature review was performed to establish the state-of-the-art in the leak detection field and to identify candidate methods. Second, a multiple-objective ranking matrix was designed and used to rank candidate techniques according to a predefined set of parameters covering pertinent technical, economic, and operational objectives.

Results indicate that no single technique or group of techniques can detect liner failure or leachate leaks with absolute certainty in either existing or planned sites. Several techniques used in combination will improve conventional water quality monitoring techniques at existing sites. In planned lined landfills, several techniques hold promise for future development.

This Project Summary was developed by EPA's Municipal Environmental Research Laboratory, Cincinnati, OH, to announce key findings of the research project that is fully documented in a separate report of the same title (see Project Report ordering information at back).

Introduction

Despite the many lined impoundment and disposal sites in use throughout the country, methods to monitor the performance of liners have not been adequately developed. When liner failures occur at a site, a monitoring system should provide warning before significant environmental damage can occur. Furthermore, such a system must be capable of locating a leak precisely so that repairs can be made. Finally, the monitoring system must be nondestructive to the liner. Efforts to determine the precise locations of liner leaks may be repaid many times in terms of reduced environmental damage, and resulting costly litigation, and by reduced costs for subsequent repairs.

During the course of this program, recommendations were developed for monitoring systems that will permit effective in situ detection of leaks in both new and existing landfill liner systems. Both solid and liquid impoundment sites were considered, but emphasis was placed on liquid waste impoundments.

Because assessing liner performance and detecting leaks varies in approach and complexity between existing and planned sites, each situation was considered separately. At existing sites, any leak detection program is almost totally site-dependent because of considerations such as site area, depth of impoundment, and the presence of waste already in the landfill. Sites still in the planning stage can be tailored to a monitoring program. Thus it may be possible to emplace a leak detection system directly under a planned site before construction, or even to select a configuration for site layout that will

readily lend itself to a routine monitoring program.

At the outset of this program, the primary objective for each candidate detection technique was the ability to pinpoint a landfill liner failure within a maximum area of 0.1 m^2 (1 ft^2). But because of restrictions placed on detection systems at existing sites (which in most cases will limit them to surface use), this goal was broadened to encompass any system that could feasibly improve current conventional monitoring techniques. Thus any system with the potential to detect a leachate plume before it contacts the groundwater was reviewed and evaluated. In the case of detection techniques applied to planned disposal sites, the 0.1 m^2 (1 ft^2) goal was retained. Thus plume detection at existing sites is distinguished from actual leak detection at planned sites.

Program objectives were met in two study phases. First, a literature review established a state-of-the-art in the leak detection field and then identified a list of possible candidate methods. Second, a multiple objective ranking matrix was designed and executed. This tool was used to rank candidates according to a predefined set of parameters covering pertinent technical, economic, and operational objectives. The program results in the information needed to set priorities for research and development and to allocate resources for future development of promising leak detection techniques.

Technical Considerations

To help define potential leak detection systems, the study identified certain phenomena that were expected to be associated with liner leaks. Various leak detection techniques for locating or identifying these phenomena were then selected. A review was also made of techniques that had been applied in various environments for a variety of purposes, as well as those that seemed to have conceptual application to the leak detection problem. Phenomena that might yield to leak detection techniques include the following:

- Leachate conductivity,
- Subgrade and landfill materials,
- Groundwater flow fields, and
- Liner and soil distress.

Various geophysical techniques might be applied to detecting these phenomena under favorable site conditions. Some of these techniques were selected for review and evaluation here based on the following criteria:

1. The ability to "sense" beyond their point of application to a depth greater than 30 m (33 yd),
2. The ability to be applied in situ without harming the liner,
3. The ability to improve conventional groundwater monitoring techniques at existing sites, and
4. The ability to detect a leak within 0.1 m^2 (1 ft^2) at planned sites.

Some geophysical techniques apply to both existing and planned sites, whereas others may be used in either one or the other.

The performance of a leak detection system depends on the site environment and the landfill contents. Any particular site may be subject to natural or cultural interferences that can degrade performance of the monitoring system.

Geophysical sensing techniques have inherent limitations on their ability to detect leaks, particularly at existing waste sites. Many of the geophysical methods are limited by the waste and background materials, which render surface measurements far from ideal. In many cases, geophysical methods may not be at all useful for detecting leaks under a site and may only be able to detect changed conditions over time in the unsaturated zone before a contaminant reaches the groundwater. Borehole methods improve the probability of detecting leaks because potentially they can reveal conditions under the site and do not have to sense through it. Borehole geophysical techniques are most useful when the distance between boreholes is not greater than about 30 m (33 yd), though this distance varies depending on soil type and conductivity of the host material. Most techniques fail to penetrate at greater distances.

Detecting leaks at sites that might undergo construction at some future date is not simple, but it is much less complex than for existing sites. A variety of sensing systems can be placed near the liner to detect the presence of leachate or its effects, or to evaluate the mechanical integrity of the liner itself. Ultimately, it may be advantageous to design a system combining several geophysical techniques for monitoring conditions such as the presence of leachate and the occurrence of mechanical failures.

At planned sites, the goal of detecting leaks within a 0.1-m^2 (1 ft^2) range becomes a very real possibility. Eventually it may be possible to design an inbuilt system to meet the needs of any site in terms of cost and technical precision. Thus a small site or a municipal landfill with nonhazarous wastes could use a relatively inexpensive system monitored quarterly or twice a year. For vast impoundments of hazardous liquid wastes, where the cost of liner failure would be great, it will eventually be possible to build in a continuous monitoring system with equipment and procedures designed for cell-by-cell monitoring and daily retrieval, processing, interpreting, analyzing, recording, and storing of liner performance data.

State-of-the-Art Review

Based on these technical considerations, a literature search was conducted to identify possible candidate methods being investigated in the laboratory or applied in the field. Five data bases were searched, including GeoRef, EnviroLine, Pollution Abstracts, NTIS, and DOD Documentation Center, followed by a manual search.

The literature review provided little information on actual leak detection techniques in existing or planned lined landfills. Considerably more information was available regarding the problem of leachate plume detection at existing sites. But in no case was successful leachate leak detection reported before it was detected by groundwater quality monitoring, which assumes fairly widespread contamination. This finding does not so much reflect the limitation of current geophysical leak detection techniques as it indicates the state-of-the-practice in groundwater quality monitoring. During the review, no cases were found in which techniques were actually being applied in the field to evaluate liner integrity.

All possible leak detection techniques reviewed in the course of the survey are summarized in Table 1. Techniques that have seen application in the field to detect a leachate plume include HF Pulse Techniques, electromagnetics, resitivity, and seismic techniques. Resistivity techniques appear to have had the greatest field application; these are followed by electromagnetic techniques, which are beginning to see wide application both for

·Multiple Objective Ranking ·Matrix

Finally, a multiple objective ranking ·atrix was structured to compare the ·andidate methodologies with regard to a ·efined set of criteria. The criteria defined ·arlier for geophysical techniques were ·clude·d. Techniques were eliminated ·om trix if they were not identified ·n the ·ure survey as having at least the potential for producing satisfactory results. Also, only techniques that posed no significant risk factors to the operators or to the environment were considered. Thus any technique that could not possibly work without substantial penetration of the dumpsite and the liner was rejected from further consideration. This limitation severely reduces the number of techniques that can be used at existing sites and also the probability of success in detecting leaks under the waste site.

The completed matrix evaluates each techniqun on the following parameters:

- Technical factors (such as range, resolution, lateral extent, flow direction, etc.)
- Sensitivity (soil type, waste type, and cultural noise)
- Data reduction (data acquisition time, interpretation time, etc.)
- Impacts (safety, site disruption, and site safety and liability)
- Economic factors (capital cost, installation cost, etc.)
- System capabilities (operator skill, portability, survivability, and availability)

Since some of the parameters are more vital for success than others, a weighted scale was devised. The weighted curve applied to the matrix parameters appears in Figure 1. All the values are given on a relative scale of 1 to 10.

Matrix Results

Matrix results are summarized and displayed in Tables 2 and 3. The average values for all parameters tend to group around 6.7, except for the two grid techniques, which are about 7.8. Clearly, no significant variation exists among the techniques. Considering the conditions under which methodologies were included in the matrix, this consistency is neither surprising nor unreasonable.

All of the techniques are very sensitive to the soil and waste type, with an average sensitivity value of about 4. This value indicates that probably none of the techniques will work in certain situations found in a typical waste dumpsite. The two grid techniques are less sensitive to the site conditions because they are only feasible for planned sites where optimum conditions can be selected.

All the values in the impacts group have very high ratings because the only techniques that were considered were those that had no significant risk factors for the operators or the waste dumpsite. Lower values were given if the technique required the use of holes for short rods on the site or if boreholes near it were necessary. Obviously, if any risk exists for the operator or the site, the technique is impractical. This limitation severely reduces the number of techniques that can be used, and with it the probability of success for detecting leaks under the waste site.

All of the values in the technical factors group for existing sites tend to be about 6.7. This result appears to be discouraging at first, and it certainly indicates the difficulty of using any of the geophysical or other techniques for monitoring or detecting leaks from an existing waste dumpsite. Clearly no single technique stands out as superior for detecting leaks in existing sites. This matrix makes it abundantly clear that a composite of techniques must be used to solve this complex problem, particularly in existing sites. Nearly all the techniques are sensitive to the various electrical properties of a leachate in the host medium. The exceptions are the seismic and acoustic mission techniques, which are sensitive to the elastic properties and density changes caused by a leak or the acoustic emission from the fluid flow from a leak. A composite geophysical survey can be designed to monitor a complex of material properties, thus enhancing confidence in the survey results.

Figure 1. Weighting curve applied to matrix parameters.

Note that techniques evaluated for planned sites received overall higher scores. This result reflects the reality of the problem described in both the literature survey and the matrix results. Landfill liner integrity and performance monitoring programs will be easier to design when they are included and planned for at the conception of a total waste disposal program. Note that despite the problems associated with geophysical techniques, they still hold greater promise of success under optimum site conditions than do the conventional monitoring methods. Leak detection at existing lined sites is and will continue to be more problematic. But skillful use of the techniques described here should often lead to leak detection before extensive groundwater contamination occurs.

Conclusions and Recommendations

Results of the survey and the ranking matrix indicate that no single technique currently exists that is applicable in all or even many situations, particularly in existing sites. Each geophysical technique has both theoretical and site-specific limitations. Further research is needed to demonstrate the advantages and limitations of a number of the candidate methods in various dumpsite configurations. Such investigations should include both solid and liquid sites in various soil types, and they should include an array of techniques used in a composite mode. The optimum configuration for planned sites that are to be monitored may be long trenches up to 30 m (33 yd) wide. This shape should reduce the range limitations that exist with geophysical monitoring techniques.

Though no single technique or group of techniques has been identified as a solution to the leak detection problem, the group of techniques reviewed and evaluated here can be applied systematically and synergistically to existing lined sites with the eventual hope of detecting leachate contamination before damage occurs to the groundwater. Cetainly such techniques should be applied routinely in conjunction with water quality sampling at any site identified as a potential problem. In the case of planned sites, several solutions hold promise for future development.

A project was conducted to develop reliable, nondestructive methods for detecting leaks in lined waste impoundments before the leachate can seriously damage the ground water. A second goal was to find a technique to locate the precise area where a known leak is occurring. After a preliminary study involving a literature review, a state-of-the-art survey, and a ranking matrix exercise, two techniques were recommended for immediate further study — acoustic emission monitoring (AEM) and time domain reflectometry (TDR). AEM determines the amplitude and frequency responses of sounds emitted when water flows at different rates through soils. TDR is a high-frequency electromagnetic technique that measures the electrical properties of materials in and around the conductors of a transmission line.

Laboratory and field studies were undertaken to evaluate the potential of these two techniques. Results indicated that AEM potentially offers a practical and inexpensive technique for leak detection and monitoring in both existing and planned liquid waste impoundments.

TDR appears to be a practical method for detecting and determining the position and extent of a leak under a small waste impoundment liner. Further testing is needed to determine the usefulness of both techniques in the field, however.

This Project Summary was developed by EPA's Municipal Environmental Research Laboratory, Cincinnati, OH, to announce key findings of the research project that is fully documented in a separate report of the same title (see Project Report ordering information at back).

Introduction

Each year about 35 million metric tons of hazardous wastes are disposed of in impoundments lined with natural or manmade materials. The liners act as barriers to impede the flow of the hazardous wastes to the underlying ground water. But presently, little information exists on the effectiveness of the different liner materials, and monitoring methods are unsatisfactory. Ground water is presently monitored through wells placed hydrologically down stream. Thus wastes must actually be present in the ground water before they are detected, and significant damage may already have occurred. No methods currently exist that can detect the source of a leak in a liner before the leachate reaches the ground water.

The purpose of this project was to develop reliable, nondestructive methods for detecting significant leaks in lined waste impoundments before the leachate can seriously

damage the ground water. A second goal was to find an economical technique that could locate the precise area where a known leak occurring in the liner.

The first step in the project was to identify and evaluate a wide range of techniques for liner leak detection. A preliminary study was conducted for this purpose (M.J. Waller, J.L. Davis, and William Kean, 1981. "Assessment of Innovative Techniques to Detect Waste Impoundment Liner Failures," EPA-600/2-84-041, U.S. Environmental Protection Agency, Cincinnati, OH). After a thorough literature review, state-of-the-art survey, and ranking matrix exercise, this earlier study recommended two techniques for immediate further study — AEM and TDR. AEM determines the amplitude and frequency responses of sounds emitted when water flows at different rates through soils. TDR is a high-frequency electromagnetic technique that measures the electrical properties of materials in and around the conductors of a transmission line.

The present study was undertaken to perform laboratory and field studies to evaluate the potential of these two techniques for detecting leaks under waste impoundment liners.

Acoustic Emission Monitoring

AEM techniques have been used for at least 50 years to evaluate stresses in rocks and metals, but their application to soil structures is more recent. Acoustic emission (AE) techniques have shown potential use in earth stability monitoring, settlement and deformation monitoring, and water flow monitoring through earthen dams. To determine the potential application of AEM for detecting leaks from lined waste impoundments, experiments were conducted to measure the amplitude and frequency responses of sounds emitted when water flows at different rates through different soils and rips in a liner material.

Methods and Equipment

Experiments were carried out with three objectives: (1) to determine whether sounds are emitted when water flows through soils and rips in liners, (2) to characterize the sounds emitted when water flows through soils and rips in liners, and (3) to determine the attenuation of these sounds in water. Laboratory studies were conducted to fulfill the first two objectives, and field studies were carried out to achieve the third.

Soil Columns

The laboratory experiments for determining and characterizing sounds produced from water flowing through soils and rips in liners were conducted in soil columns held by a polyvinylchloride (PVC) duct 4 m long and 30 cm in diameter (Figure 1). Different heights of soils could be placed in the column and water could be passed through the soils at different known rates. Some soil column experiments were conducted using 30-mil PVC sheets with either 5- or 15-cm rips. A microphone was placed in the soil of the columns and the sounds were amplified, processed, and displayed. Special care was taken to reduce unwanted background noise. A spectrum analyzer capable of capturing transient events was used to process the data. The amplitude and frequency response of the output signal was displayed on an oscilloscope, recorded on a digital tape recorder, and plotted on an X-Y plotter.

Figure 1. Schematic diagram of the experimental acoustic emission test arrangement

Electronic Equipment

The electronic equipment used to detect, amplify, process, and display the acoustic data included an acoustic receiver (Figure 2), a Weston Acoustic Emission Monitor* with variable gain amplifier of 1 to 5000, a Weston AEM filter unit modified to cover a frequency range of 20 Hz to 5 KHz, a Nicolet 446B mini ubiquitous spectrum analyzer, an analogue X-Y plotter, a sweep oscillator, and a loudspeaker.

*Mention of trade names or commercial products does not constitute endorsement or recommendation for use.

Measurement Procedure

The method generally used for laboratory measurements was to place the microphone in the soil being tested (as shown in Figure 1) and let the water flow through the soil. The height of the soil in the column varied from 70 to 150 cm. The microphone was placed 15 cm above the bottom of the soil column (i.e., above the 45-mesh screen). The flow rate and the acoustic spectra were measured, and the spectral data were plotted on the X-Y recorder. The water level was recorded on an X-time recorder. After about every 30- to 40-cm drop in water level, the flow was stopped and a spectrum of the background noise spectra was obtained and subtracted from the response obtained when the water was flowing through the soil.

Soils Tested

The soils used in these experiments were 20/30 Ottawa sand and a pea gravel, with an average grain size of 0.7 mm. The grain size of more than 90 percent of the pea gravel sample fell between 25 and 5 mm, with the remaining portion between 5 and 1 mm.

Water Levels

The water level varied from about 3 m above the soil to just above the soil in each of the experiments; thus falling water head levels occurred during the experiments. The flow rates typically were varied from 0.3 to 1 cm/sec.

Attenuation of Sound in Water

An audio frequency sweep oscillator working over a frequency range from 20 to 500 Hz was used to drive a loudspeaker specially designed to operate underwater. The standard AEM system used throughout these studies was used as the receiver. The AE sensor was moved away continuously from the loudspeaker at a depth of 1 m in a lake whose depth was 2 meters. The sound amplitude over the frequency spectrum was measured as the distance between the source and receiver was varied from 0.2 to 5 meters. The attenuation was measured at 10 dB/m over the frequency range of 100 to 500 Hz in the lake. It was observed that the attenuation of the sounds decreased significantly as the frequency was increased into the kilohertz range.

Results and Conclusions

1. Acoustic signals are emitted when water flows in a turbulent mode through soils. Acoustic signals at frequencies up to 500 Hz are emitted when water flows at rates of 0.3 to 1 cm/sec through a sand and a pea gravel.

Figure 2. A block diagram of the electronic equipment used to detect acoustic signals emitted when water flows through soils.

2. The flow must be turbulent for acoustic signals to be emitted. Turbulent flow occurs at rates down to 0.1 cm/sec (1 gpm in the 30-cm-diameter test column) with the sands tested.
3. The amplitude of the sounds increases as the turbulent flow rate increases. For example, at a flow rate of 0.3 cm/sec (4 gpm through the 30-cm-diameter test column), the amplitude of acoustic signals through coarse-grained soils is about equal to the background noise likely to exist at liquid impoundment sites. But at an increased flow rate of 1 cm/sec (10 gpm in the 30-cm column), the amplitude is 100 times greater.
4. At a flow rate of 0.3 cm/sec, the sound amplitude increases with increasing variation in soil grain size.
5. At a flow rate of 0.3 cm/sec, the sound amplitude decreases with increasing soil density.
6. The sounds emitted when water flows through soils have significant amplitude at frequencies up to 500 Hz, and they have a peak amplitude between 100 and 200 Hz.
7. The attenuation of sounds between 100 and 500 Hz is 10 dB/m near the surface of a lake.
8. No significant sounds were detected when water flowed at rates up to 1 cm/sec through either a 5- or 15-cm rip in a 1-mm-thick PVC liner material.

Recommendations

1. Determine the spectral response for background sounds emitted at existing waste impoundment sites at frequencies up to 500 Hz.
2. Determine the attenuation of sounds at frequencies from 20 to 500 Hz in a typical waste impoundment site environment.
3. Determine the advantage of different arrays of acoustic sensors for detecting leaks at waste disposal sites.
4. Determine the spectral characteristics for acoustic signals emitted from leaks with known flow rates at a field model of a liquid impoundment site.
5. Determine the spectral response of sounds emitted when plastic liner materials creep.
6. Determine whether AE occurs when water flows through a silt or clay soil.

Time Domain Reflectometry

TDR is a wide-frequency bandwidth, short-pulse-length measurement technique that is sensitive to the high-frequency electrical properties of the material in and around conductors of a transmission line. The high-frequency (10^8 to 10^9 Hz) dielectric properties of water in its liquid state are about 20 times greater than the high-frequency dielectric properties of dry geologic materials: thus TDR is primarily sensitive to changes of water content in geologic materials and relatively insensitive to changes in soil type and density, temperature, and pore liquid salt content.* In materials with a relatively uniform water content, TDR is sensitive to changes of soil and rock type. This method is also sensitive to changes in the phase of the water molecule, and thus frozen or unfrozen wet soils. In addition, TDR can detect either water- or air-filled fractures and voids in the materials along the transmission line.

Leaks from liners of waste impoundments into the soil below are likely to have different electrical properties from those of the host material: thus TDR can measure leachates in the soil material along a transmission line. The TDR technique, using transmission lines placed under a liner offers the significant potential of being a practical method for detecting small leaks from waste dump sites.

*Topp, G.C., J.L. Davis, and A.P. Annan, "Electromagnetic Determination of Soil Water Content: Measurements in Coaxial Transmission Lines," Water Resources Research, Vol. 16, No. 3, June 1980.

The electrical measurements in soils are carried out by placing a transmission line consisting of two electrical conductors in the soils to be tested. Commercial high-frequency transmission line conductors are usually up to 1 cm apart, but it is intended to design and use transmission lines whose conductors are as far apart as possible — on the order of meters. Before a practical TDR system can be developed for detecting leaks under waste impoundment liners, tests are needed to determine the practical problems of increasing the spacing between the conductors.

The objective of this study was to determine the size of an anomaly (simulating a leachate) that could be detected as the spacing for the transmission line conductor was varied.

Background

TDR has been applied to measurements of geologic materials for fewer than 10 years, and therefore much of the work to date has been carried out to determine the practical applications and limitations of the technique. The main application of TDR for more than 30 years has been for testing transmission line cables such as those used in radio and telephone communications and in high-voltage transmission lines.

The electrical properties of geologic materials, especially soils, are very complicated at first glance. But over the frequency range we are interested in (10^8 to 10^9 Hz), the dielectric constant is primarily sensitive to changes in water content and has a relatively weak sensitivity to changes in soil type and density, temperature, and soluble salt content. TDR has shown excellent potential for carrying out useful electrical property measurements of geologic materials.

The TDR equipment is coupled to the geologic medium by a transmission line. A transverse electromagnetic (TEM) wave propagates along the transmission line in the dielectric material between and around the conductors, which act as guides for the waves. The propagation velocity and attenuation characteristics of the TDR signal in the transmission line are dependent on the electrical properties of the material in the transmission line.

Methods and Equipment

Experiments were first conducted in the laboratory to determine how the TDR signal pulse rise time response varied as the conductor spacing of the transmission line increased. Next, experiments were carried out to determine the physical size of the anomaly in the transmission line that could be detected by the TDR system as the conductor spacing was varied. Finally, tests were con-

ducted to determine the change of TDR response as the position of the anomaly was moved in the transmission line.

The equipment consisted of a TDR unit, an X-Y plotter, a parallel transmission line, an electrical connector to connect the TDR unit to the transmission line, and boxes filled with dry sand to simulate an anomaly. The TDR instrument used for these experiments was a Tektronics Model 1502 cable tester, a portable field unit with pulser, receiver, and display units in one package. The transmission line was a parallel wire transmission line. The two conductors of the line were made of 6-m-long aluminum tubes with a 5-cm outside diameter. These tubes were supported on a wooden frame so that the spacings between the tubes could be varied (10, 20, 40, 60, 80, 100, 120, 150, and 200 cm). A special electrical connector was designed and built to connect the TDR unit to the conductors at the different spacings. The connector consisted of a 50- to 200-ohm Balun transformer and two sheets of metal to connect the transformer to the aluminum tubes. Figure 3 is a schematic diagram of the TDR unit, the connector, and the parallel transmission line.

The anomalies that might be found in the field were simulated in the laboratory by boxes (15 cm^3) filled with dry sand and placed side by side and on top of each other when the size of the overall anomaly needed to be increased. The sand had a dielectric constant of 3.5. The boxes of sand were the equivalent of a water-saturated soil in a soil host material with a volumetric water content of about 20 percent. The electrical losses in the air and sand were negligible to the TDR pulse used. This arrangement provided a satisfactory initial model of an actual field setup under a waste impoundment liner.

Results and Conclusions

Findings of the project were as follows:

1. The TDR pulse signal rise time increases with the spacing between the conductors of a transmission line. The attenuation to the higher frequencies in the pulse increases with the frequency, and thus the TDR system resolution decreases as the spacing increases. In other words, the size of the anomaly in the transmission line must increase with the transmission line spacing to produce the same TDR-reflected signal amplitude.
2. The TDR signal amplitude does not vary when the TDR signal travel time in the anomaly is less than or equal to the total travel time necessary for the signal to propagate through the anomaly. As the electrical length of the anomaly decreases below the pulse travel time in the anomaly, the signal amplitude decreases.
3. The TDR signal amplitude varies slightly with the height of the anomaly (i.e., the dimension whose axis is perpendicular to the plane of the conductors in the transmission line varies as long as the height of the anomaly is at least three times greater than the diameter of the conductors).
4. The amplitude of the TDR signal is greatest when the anomaly touches both conductors of the transmission line. The signal amplitude decreases significantly as the width of the anomaly decreases relative to the spacing of the conductors. The signal amplitude decreases less rapidly if the anomaly is in contact with either of the conductors.

These findings lead to the conclusion that a cube-shaped anomaly whose sides are equal to at least half the spacing between the conductors will have a TDR signal amplitude of about one-fifth the maximum signal amplitude that would occur if the transmission line penetrated an anomaly that was very large relative to the spacing of the transmission line conductors. This generalization will be affected by a number of factors not included in the studies. The electrical loss properties of the materials likely to be found in the field will reduce the TDR signal amplitude. Thus the size of the anomaly will have to be increased to increase the reflected TDR signal amplitude. The electrical property contrast of the leachate-saturated soil relative to that of the host soil under the waste impoundment may not be as great as the electrical property contrast used in the model. Thus the reflected signal amplitude may not be as large in the waste site environment.

The model used in these experiments only tested the TDR response in transmission lines whose maximum spacing between the conductors was 2 m. Larger spacings between the conductors are practical using the same TDR unit, but experiments to determine the maximum spacing of the conductors still need to be carried out.

The TDR technique appears to be a practical method for detecting and determining the position and extent of a leachate under a small waste impoundment liner. A cube-shaped leak with dimensions on the order of one-half the space between the conductors of the transmission line is about the minimum practical size that can be detected using the TDR technique.

Recommendations

The following recommendations should be followed before a TDR system is placed in the field under a waste impoundment liner:

1. Carry out experiments using simulated leaks over transmission lines at different conductor spacings placed in a sandy soil about 1 m thick.
2. Based on the results of the above experiments, design a series of transmission lines with different spacings between the conductors and placed in a sandy soil under a lined pond filled with water. Vary the lengths of the transmission lines up to about 30 m. Use controlled leaks in the liner to test the ability of the TDR system to detect leaks of different sizes and positions around the transmission lines.
3. Carry out a TDR system field design configuration and cost analysis after the above tests have been made.
4. Design TDR equipment specifically for detecting leaks at actual waste impoundment sites. Possibly a higher-power pulse of longer duration would make the TDR system more economical for detecting leaks at large waste impoundment sites.
5. Determine the best materials for transmission line conductors to minimize corrosion in a waste dump environment.
6. Determine the high-frequency (1 to 1000 MHz) electrical properties of some leachate-saturated soils and of soils typically found under waste sites.

The results of the recommended research will help define the usefulness of the TDR technique for detecting leaks and for determining the extent of leaks from a waste impoundment liner. Such studies will also aid in the design of a practical TDR system for monitoring leaks from waste dump sites.

INTRODUCTION AND FRAME OF REFERENCE

Impoundments or ponds are installed to store potable water as well as process water, e.g., pregnant solutions and barren solutions for recycle and as evaporation ponds to dispose of excess or contaminated water. Water impoundments can also be used to "age" recycled tailings water before it returns to the mill.

In very cold climates with snow and ice cover during winter, an interesting problem arises in controlling water inventories in ponds below the ice cover since the surface level is not visible from above. A public outcry arose when treated effluent from a pond at KEY LAKE MINING overflowed the impoundment under an ice cap about a year ago in Saskatchewan. Where the pond is covered in ice or snow in winter and where it contains solution that is not designed for discharge as an effluent, it is important to install a

remote level sensor in the pond so that inadvertent overflow can be avoided. Details of how this is now done at KEY LAKE can be requested from:

KEY LAKE MINING CORP.

Bernard Rosner
Engineering Manager

When water is scarce or expensive, it becomes necessary to conserve it. Interestingly, at RÖSSING URANIUM LTD. in South West Africa/Namibia, the tailings pond itself is used to store process water for recycling. In the exceptionally hot, dry, and windy climate in the Namib Desert, RÖSSING water losses through evaporation are enormous. As part of their water conservation drive, many kinds of liquid films and other measures have been tested as a way to reduce evaporation from the tailings pond. After testing various alternatives to reduce evaporation, it was concluded that the most effective and only practical way is to reduce the surface area of the pond in the tailings impoundment. This was done by withdrawing water from the tailings pond and letting the waterline recede. Not only are evaporation losses cut in this way but undoubtably, by reducing the hydrostatic head on the porous pond, rate of seepage will have declined too.

COTTER CORPORATION at Canon City has constructed a large lined tailings pond which also serves as an evaporation pond. In their case, no tailings water is recycled to the mill.

The above are two cases where different types of tailings impoundments are used as evaporation ponds or for water storage. Quite often, however, separate impoundments are installed as can be observed in the photograph of a modern Witwatersrand tailings impoundment where runoff and seepage is collected and evaporated in the ponds along their base.

Seepage from ponds can be considerable and, increasingly, impermeable linings are required to reduce water losses or to prevent environmental damage. With the recently increased awareness and emerging regulatory requirement to protect ground water quality, impermeable lining of water impoundments will increasingly be installed to meet permit requirements. Linings used include clay, bentonite stabilized soil, or plastic membranes.

Care should be taken in selection the type and grade of liner material as well as in applying the membrane, and attention should also be given to controlling the quality of the membrane delivered to the site to be sure that it is the same as that selected.

RUNOFF IMPOUNDMENTS ALONGSIDE WITWATERSRAND TAILINGS

CONCLUSIONS ABOUT POND LININGS

1) There have been many failures in synthetic impoundment linings. These have been due to improper selection of materials, improper installation, or improperly designed earth work support base for the membrane. To be able to function, the complete lining and support system must be correctly selected, designed, and installed.

2) Liner and lining installation suppliers are the major source of information on linings. They can recount prolific cases where their competitors' product failed, and their own is always the best and failure-proof.

3) Adequate means of detecting leaks early can be installed or used to survey impoundments early to find and repair leaks before serious damage is done.

4) When properly selected and installed, plastic liners can do a good job in storing liquids.

5) Investigation and discussion lead to the conclusion that there may be no such thing as a perfect lining. No matter how good the quality control during its application when hydrostatic pressure is applied, plastic liners invariably leak to some extent. The key is to keeping the extent of the leaks "negligible."

6) If seepage prevention is to be prevented, it is wise to apply the plastic membrane over a substrate that is itself impermeable, e.g., bentonite stabilized soil.

7) Small ponds, say 2,000-3,000 m^2 (20,000-30,000 ft^2) in surface area can be readily easily lined, but when large ponds of tens of acres and up are lined, wave action plays an important role and berm design must take this into account to avoid problems.

IMPACT OF EVAPORATION PONDS ON THE ENVIRONMENT

Evaporation ponds are used to dispose of excess contaminated or high TDS solutions from mine-mill operations. For example, where bleed streams from uranium leaching operations cannot be discharged because of permit restrictions and where metallurgical recovery problems or corrosion problems would result if a salt bleed is not achieved, the logical alternative is to dispose of it by evaporation in a shallow impermeable pond. In the U.S.A., usually these ponds are lined with plastic membranes. Many of the Witwatersrand gold milling operations collect runoff water from their tailings impoundments and dispose of it in evaporation ponds at the base of the impoundments.

As water evaporates from these ponds, the remaining solution of course becomes correspondingly more concentrated and the greater the need is to keep it contained. There are two potential problems with evaporation ponds. Firstly, they can spring a leak, the consequences of which are more serious the more concentrated their content has become. The second problem is how to dispose of the salts that accumulate and how to prepare an evaporation pond for abandonment, say at the closing of a milling operation. Covering over an evaporation pond and revegetation of the site, possibly after applying an impermeable cap to prevent water from seeping in, may be satisfactory for awhile, but will it be so after several decades or after a century or two?

If an abandoned evaporation pond is not capped with an impermeable liner but is merely covered over with soil, the real possibility exists for seepage from the surface to become

perched on the top of the liner where the salt contents will redissolve and migrate upwards by capillary action to the surface where it would likely destroy vegetation, result in surface erosion, and contaminate surface runoff. Similarly, if the pond is constructed over a porous base, the question could be asked as to how long the membrane will remain intact before becoming ruptured through natural forces and allowing a now highly concentrated solution to seep to groundwater below.

In some parts of the world, the term "evaporation pond" may be loosely used as the rate at which water is lost from the pond seems sometimes to exceed the rate of evaporation which indicates possible solution losses through seepage. Some sites where the natural base material is already highly impermeable in any case are ideal for evaporation ponds.

When an evaporation pond is to be used, the ultimate disposition of the concentrated salts and final closure of the site should be carefully considered in advance, as well as the consequences of a leak developing.

LINING MATERIALS FOR PONDS AND WATER IMPOUNDMENTS

GIROUD and FROBEL (1984) reviewed geomembrane products providing some insight into what a geomembrane is. Also provided is a list of liner suppliers, fabricators, and installers. Finally, a report by GUNDLE LINING SYSTEMS, INC. provides further insight into liner materials. The list of lining materials suitable for evaporation ponds is growing steadily. Lining materials may consist of:

- Plastic Geomembranes
- Fibre Reinforced Polymer Membranes
- Clay Linings with Membranes
- Clay Linings
- Bentonite Stabilized Soil
- Sprayon Polymer Liners

HYDROSEAL-PROCESSED BENTONITE

In addition to the liner materials and suppliers listed below, mention should be made of an activated bentonite lining material that has become popular in South Africa recently. The vendors claim to have installed 2 million m^3 (20 million ft^2) of pond linings over just a few years of operation. The vendor also applies the material and installs the lining:

AQUASAVE PTY LTD.
Post Office Box 68288
Bryanston 2017
(011) 789-1206
Chris Lee

The bentonite is spread out manually at 10 Kg/m². The hydroseal-processed bentonite is usually not mixed into the soil but is spread in an undiluted layer. The bentonite costs R290/t, and the complete lining can be installed for R5.00 (U.S. $2.50/m²) of which R2.90 ($1.45/m²) is for the bentonite. This is claimed to be much less than the cost of synthetic membranes.

Two laborers can spread 5,000 m³/d. The bentonite layer swells to about 12 times its original volume. The lining has the advantage of being flexible and self-sealing.

In the U.S.A., bentonite for pond linings would be supplied by:

AMERICAN COLLOID COMPANY
5100 Suffield Court
Skokie, IL 60077
(312) 966-5720
Telex: 724-413
Brigitte Mattison

AMERICAN COLLOID COMPANY suggests the application of their product as a soil-bentonite mixture, which is quite different to the way that it is applied by AQUASAVE. AQUASAVE claims that sand-bentonite mixtures work particularly well only if the soil consists of very clean sand.

SELECTION AND INSTALLATION OF LININGS

RANDOL INTERNATIONAL attended a geomembrane and geotextile conference and visited several mine-mill complexes where membrane linings are used. It was found that of the small number of membrane users in the mining industry for water impoundments or evaporation ponds that were visited, several had experienced problems.

It is essential that lining applications be regarded as lining systems consisting of the earth or clay base, the lining material with appropriate seams, and the way it is anchored into the ground around the pond, etc.

Membrane linings are routinely used on heap leaching operations as both pregnant solution and barren solution ponds. It is critical that appropriate membrane material be selected for the parts that are exposed to sunlight. For example, PVC linings work well as long as they are kept underwater. If they are exposed to the sun and air, PVC deteriorates very fast, becomming brittle. For this reason, Hypalon or high density Polyethylene lining are usually installed for the sides and exposed parts of impoundments.

In heap leaching applications, linings of the usually small ponds do not appear to present problems, except when occasionally an engineer drives across the membrane on an

Volclay
Landfill Sealants provide effective environmental protection from leachate pollution

American Colloid Company has been in the business of producing bentonite clay sealants since 1924. The company is the world's largest privately-owned bentonite mining company and operates processing plants in five states and several overseas locations. It has supplied bentonite sealant materials for almost one thousand landfill, lagoon and tank farm installations throughout the world.

Through its years of service to municipalities and other waste-containment operations, American Colloid has developed sealants specifically designed to be resistant to highly contaminated leachates commonly found in community waste or industrial landfills. Natural bentonite clays completely lose their sealing properties in the presence of landfill leachate through various contamination mechanisms. There are now four major types of Volclay landfill sealants:

SG-40 for capping landfills

SLS-71 for capping and lining municipal waste landfills

SLS-70 for industrial and hazardous waste landfills

SS-100 for extremely hazardous industrial landfills or lagoons

3581

What is Volclay?

Volclay is produced from a special type of high swelling sodium montmorillonite (sodium bentonite). It has a unique molecular structure that captures water molecules, with the result that the bentonite expands up to 13 times its dry volume when wetted. The molecular structure is similar in several respects to ordinary clay, but the presence of sodium ions accounts for its ability to swell to a much greater volume than natural clay or other types of bentonite when saturated with water.

These unique swelling properties play a critical role in Volclay's effectiveness as a soil sealant.

How Volclay works

When a comparatively small amount of Volclay is mixed with soil and wetted, the Volclay particles swell and fill the voids between the soil particles. This creates a barrier that effectively stops further seepage through the soil. The swollen Volclay becomes a tough, highly flexible mastic that naturally expands and moves to self-seal any cracks that develop in the supporting soil. Thus, earth settlement and small ground movements which may damage membrane liners, native clay liners, or rigid liner systems, will not damage a Volclay-soil liner.

Volclay liner and cap for new landfills

With today's stringent construction regulations, both municipal and industrial waste landfills must be properly sealed to prevent leachate pollution of ground water supplies and nearby streams and rivers.

American Colloid's Volclay landfill sealants provide a positive and economical method to prevent leachate seepage from landfills. The method illustrated below provides the security of complete encapsulation of waste materials by Volclay barriers.

Volclay slurry wall and cap for existing landfills

Many existing landfills are being closed down every year because of leachate pollution of ground water supplies, streams and rivers. However, merely closing them down does not control the long-term problem of leachate spreading through permeable soil and rock strata adjacent to such landfills.

Encapsulation, using the double barrier approach illustrated below, provides the answer to leachate migration. A slurry cut-off wall, constructed with contaminant-resistant soil sealants from American Colloid, prevents leachate migration by forming an impervious barrier around the source of pollution. The Volclay-soil cap prevents rainwater percolation.

American Colloid Laboratory and Technical Service

American Colloid laboratory testing is provided as a free service to supplement services from independent soil testing laboratories.

These tests are used to determine the appropriate grade and Volclay application level to effect a seal.

Volclay Product Compatibility Testing

American Colloid Company's contaminant-resistant products (SLS-70, SLS-71 and Saline Seal 100) have been extensively tested at American Colloid's laboratory and at independent laboratories against numerous organic and inorganic leachates that are known to either stop or reverse the swelling of untreated bentonite. Compatibility testing has repeatedly shown that specially-treated contaminant-resistant Volclay products outperform other untreated bentonite products. In addition to laboratory testing, these contaminant-resistant products have been used in hundreds of different projects and applications throughout the world with excellent success.

Our on-going testing program has resulted in a broad data base from which product recommendations are made for landfill applications.

Pore Volume Displacement Method

The sealing efficiency of a contaminant-resistant Volclay product with a specific leachate is determined by means of a permeability test. To conduct a permeability test properly, sufficient quantity of a leachate must contact and pass through a Volclay-soil specimen in a permeter unit until such time that steady state permeability conditions exist. This generally requires two to six pore volume displacements, depending on the leachate constituents. Reliable testing for contaminant-resistance over the life of a project commonly requires upwards of 20 pore volume displacements.

(Curve per Geraghty & Miller Groundwater Consultants)

The diagram above shows what typically occurs during the early stages of a permeability test prior to attaining steady state conditions. Accelerating the permeability test by means of unrealistic hydraulic gradients or unrealistic contaminant concentrations will not provide useful information about the long term effectiveness of such products in actual field conditions. Thus, permeameter test columns at American Colloid's laboratory are run at hydraulic gradients of 5 to 20, which is the range in which Darcy's Law is valid. In addition, contaminant-resistant Volclay products are exposed to actual leachate concentrations for whatever duration is necessary to achieve steady-state conditions.

Applying is easy, can be accomplished with readily-available mechanized equipment

Volclay mixed blanket application method

Soil Conditioning After finish grading has been achieved and excessively large rocks (larger than ⅓ the thickness of the Volclay-Soil liner) have been removed, a water truck is used to adjust the soil to optimum moisture content (8%-16% for most soils)

Application of Volclay Sealant Readily available equipment such as a bulk lime spreader or seed spreader may be used to apply the required amount of Volclay sealant. Manual application is also practical. Bags of Volclay weighing 100 lbs. are placed in a marked grid pattern on the surface of the area to be sealed. Bags are broken open and spread manually over the grid according to the specified application rate per square foot of area.

Blending Volclay with Soil A rotary tiller or roto tiller, with an adjustable depth control provides vigorous mixing which is necessary to achieve a homogeneous Volclay-soil blanket. An agricultural disc is sometimes used initially to loosen the soil prior to rototilling

Compaction The Volclay-soil mixture is compacted to a minimum of 85% Modified Proctor with a wobble wheel or steel wheel vibratory roller. A sheepe foot roller should not be used.

Top Cover A 12" to 18" porous cover is provided over Volclay-soil bottom liners to facilitate drainage to collection pipes. An 18" layer of native soil is applied over a Volclay-soil landfill cap to provide a protective cover

An effective barrier to leachate pollution from existing landfills

Preventing leachate migration from existing landfills is possible with the slurry trenching construction technique and American Colloid's contaminant-resistant sealants. In the illustration, note that the trench is keyed into a natural impervious layer which prevents further migration of the leachate. The trench is composed of a well-graded backfill and contaminant resistant SLS-70 or Saline Seal 100

SPECIAL VOLCLAY FOR SLURRY TRENCHES

DESCRIPTION	TYPICAL MIX RATIO
A 90 barrel yield* 200 mesh bentonite	1 part Volclay to 15 parts water
A 125 barrel yield* bentonite	1 part Volclay to 22 parts water
A 70 barrel yield* Wyoming bentonite to be used specifically to resist contamination in excess of 100 000 PPM TDS	1 part Volclay to 12 parts water

*Based — API

Constructing the slurry trench

The first step in slurry trench construction is to excavate a trench from grade to approximately three feet into an aquaclude such as bed rock or an impervious clay strata, while keeping the trench filled with a Volclay-and-water slurry. In the illustration below, the hydraulic excavator has "keyed" the trench into an impervious clay layer under a full head of bentonite slurry

Because the Volclay bentonite slurry has a slightly higher specific gravity than water, it creates a positive hydrostatic head that stabilizes the sides of the trench to prevent collapse. The Volclay bentonite slurry also interacts with the sides of the trench to create a seal that tends to hold soil particles together. Because of this, it is possible to excavate a trench 3 feet wide and over 250 feet deep (although 20 to 50 feet is more common) with minimal danger of sidewall collapse.

As trench excavation continues, additional slurry is added to compensate for each bucket of spoil removed.

After the trench has been keyed, the final step, of backfilling can begin. The backfill consists of additional Volclay and soil which have been mixed in the proper ratio to provide an impervious barrier. In the illustration, controlled back-filling has begun where the trench starts. The addition of backfill displaces spent slurry which is then pumped out and either returned to the trench or disposed of as excavation proceeds

Proper backfill is the key to long-term barrier effectiveness. American Colloid laboratory analysis can make an advance determination as to whether the spoil from the trench is suitable for backfill. If not, they will recommend a backfill, the right Volclay product, and the proper mix for an optimum barrier wall

Volclay Sealants are protecting communities all over the country from leachate pollution

This beautiful setting could be a park or just a green field. In actuality, it is a landfill of leather scrap over 30 feet deep. The fill is encapsulated by a Volclay liner and protected from rainwater intrusion by a Volclay Cap. Because the leather scrap produces a very springy fill, only Volclay with its flexible membrane and its ability to self-seal after flexure was able to meet the stringent requirements for this landfill.

Volclay also minimizes the escape of gases from the landfill and provides a beneficial substrate for grass-type foliage. It requires only annual mowing to inhibit the growth of woody plants whose roots might penetrate the Volclay membrane.

inspection, forgetting that his pickup truck is fitted with studded snow tires. Often these ponds are smaller than one acre, which seem to be easier to design.

QUIVIRA MINING COMPANY

QUIVIRA MINING COMPANY disposes of a high TDS bleed from their acid leach uranium circuit. The bleed would consist mainly of raffinate at a very low pH with a high TDS level, including sulfate and chloride ions.

QUIVIRA MINING COMPANY is not the only uranium milling company in New Mexico that experienced similar lining problems in their evaporation ponds. Similar problems were reputedly experienced by municipalities until more was learned about building large impoundments. The experiences of QUIVIRA MINING CO. are worth recounting as they provide an insight into several of the pitfalls which an operator is likely to encounter which are not obvious in advance, yet can render ponds unworkable or result in the need for major repairs.

Many years ago, before the U.S.A. became "ground water quality conscious," QUIVIRA used to discharge their bleed solutions to three unlined ponds (E4, E5, and E6 in the diagram). These were unlined and resulted in seepage losses. Later, ground water monitoring defined a seepage plume radiating out from the tailings pond and indicated by chloride levels which would have originated in tailings solution or seepage from ponds E4, E5, and E6. It became clear that evaporation ponds would have to be lined.

QUIVIRA next installed a lined pond (No. 8) at the toe of the tailings dam. PVC lining was for the floor and chlorinated polyethylene (CPE) for the sides. When bleed solution flowed into this pond, an unexpected problem arose. Large gas bubbles formed under the membrane forcing it to "float" to the pond surface in places in such a way that the gas could not be removed. The gas was found to be CO_2 evolving from a reaction between acid seepage from the dam and carbonates in the alluvia beneath the pond. At the time, it was thought that the CO_2 was generated by the acid bleed solution which had been discharged to the pond before the lining was installed. Several "burpvalves" were installed by the WATERSAVER COMPANY as a means to get rid of the gas, but these failed to solve the problem.

A soil covering was applied to try and weigh the liner down, but this did not work either. A switchblade artist could have released the gas, but this would have left a leak. Eventually, Pond E8 was abandoned. Inspection today shows that where the PVC floor lining is covered by sediment, it appears to still be plastic and "in good shape." However, where exposed to the sun and heat, plasticiser has evaporated, and the PVC has decrepitated.

35 SETTLING $BaSO_4$ PONDS

Pond 10 was designed and installed by JACOBS ENGINEERING in 1976, also at the toe of the dam. Even though no effluent had been discharged to this pond before the lining was installed, the same gas bubbles plagued this pond until it too had to be abandoned. It was then established that the gas was CO_2 generated by a reaction between the carbonate alluvia and seepage from the main tailings dam a couple of hundred yards away.

Ponds 11-15 were installed also with PVC floors and 20 mil. CPE on the sloping walls in 1977-1978, again by JACOBS ENGINEERING, with membranes supplied by PANASALL. This time, the ponds were located far enough away from the tailings pond to avoid gas bubbles. The membrane panels were installed from rolls with their seams parallel with the long sides of ponds. The walls were sloped at a gradient of 2.5:1 against sandy material that had been banked up. These ponds are large. The five ponds total 110 acres and cost $2 million in 1978.

Several problems have been experienced:

- The steep sides are vulnerable to wave action. Slope stability of the earth walls was inadequate, and the soil support beneath the membrane sloughed inward putting the liner under tension.

- The membrane panels were factory joined with seams parallel to the wall of the dam. These seams have failed in places due to the tension from the sloughed banks.

- Rodents have tunnelled to the membrane from below and gnawed holes through the plastic. The holes allow water to reach the underside of the membrane, allowing the earthen wall to become wet and plastic.

EXISTING DESIGN

HINDSIGHT RECOMMENDATION

Engineers on the site find that the 2.5:1 slope of the embankments combined with wave action has been the main cause of liner failure. The failures were exaggerated by improper panel orientation, rodent holes, membrane embrittlement, and seam failure on the 20 mil. CPE membranes used for the sides. The basic design of these ponds appears to be failure prone regardless of the membrane type selected.

Ponds 16-21

Ponds 16-21 were designed and installed by KERR McGEE CORP. along the lines of Ponds 11-15. These ponds, covering 160 acres, were installed in 1979-80 at a cost of $3.2 million. These ponds also have PVC floor panels but with hypalon sides. The basic configuration of the ponds is similar to that of the earlier ponds installed by JACOBS ENGINEERING with 2.5:1 slopes.

Once again, wave action against the unstable slopes of the earth pond walls has caused the wall material to slump behind the hypalon membranes. This has caused tension in the membrane and has resulted in failure. Again, the membrane panels are oriented parallel to the walls making them more susceptible to seam failure than if the panels were oriented across the slope.

Again, rodents have gnawed holes in the membranes on the exposed sides, allowing moisture to get behind them which, in conjunction with wave action, fluidizes the supporting pond walls.

MEMBRANE REPAIR

Membrane damage, apart from the rodent holes which are easily patched, usually takes the form of seam failure where the earth embankment walls have slumped and put stress across the seam.

The cost of retro-changing the slope profile of the impoundment walls would be exorbitant. To date, the repairs that have been made involve replacement of parts of the membrane panels. Several alternatives have been tested:

1. CHEVRON industrial membrane (CIM) painted over fiberglass reinforcement to make a new membrane to span the rips in the hypalon liner has been applied on the side of pond No. 16.

   Five gallons of CIM were required to cover an area 15' long x 2' wide at a cost of $15/gallon plus the fiberglass. Roller application of CIM was found to be messy and time consuming, although QUIVIRA MINING described CIM as a "very good product."

2. Hypalon patches on Hypalon. These proved difficult to glue.

3. CPE patches adhered to hypalon using STAFF INDUSTRIES' CC801 adhesive works very well. Expansion flaps are left in the inserted CPE panels. Liberal amounts of adhesive are applied to both membrane surfaces before pressing the two together. The glue works best if applied in warm weather. It is supplied by:

STAFF INDUSTRIES, INC.

Detroit, MI 48201

SUGGESTED ALTERNATIVE EVAPORATION POND DESIGN

Since wave action appears to cause a steep wall to seek an equilibrium low angle beach, QUIVIRA MINING believes that the beaches of evaporation ponds should be constructed that way in the first place.

At QUIVIRA MINING, it has been observed that when the water level drops so that waves can run up a shallow beach, then there are no slopes to become unstable. The shallow beach areas also seem to become protected by a layer of silt. In order to get the volume required in the ponds, it is necessary to have an adequate depth. To achieve this, an "inverted tophat" profile design has been suggested. Such a design would require more real estate but, hopefully, would avoid the expensive maintenance and potential for leaks. The profile for this design is illustrated below.

OLD "FARM-TYPE" POND PROFILE

PROPOSED IMPROVED "INVERTED TOP HAT" PROFILE

QUIVIRA MINING COMPANY was one of the pioneers in applying lined evaporation ponds, and they have considerable experience with pitfalls and problems in this area. A QUIVIRA engineer who has been directly involved in solving these problems and who has also conceptualized improvements may now be available for consultation since QUIVIRA operations have shut down due to weak uranium prices:

KEY LAKE MINING

KEY LAKE MINING CORPORATION installed Hypalon linings in two reservoirs and five monitoring ponds at their Saskatchewan operation. These linings were installed some months in advance of the impoundments being filled. In this case, the linings failed even before the impoundments were used. Apparently, delamination of the membrane occurred.

Industry observers point out that if the individual strands of nylon reinforcement are too close together, i.e, if the scrim is too tight, then the bonding area in the spaces between fibers is too small for a good bond between the two layers of membrane. This observation seems plausible and is an aspect of thermobonded reinforced membranes that is worth being congnisant of.

A PUBLICATION FOR LINING SYSTEM USERS FROM SCHLEGEL LINING TECHNOLOGY. VOL. 1, 1984

ARE GEOTEXTILES NECESSARY WITH THICK LINERS?

Puncture and Tear Resistance Not Necessarily Improved

POLLUTION ENGINEERING magazine in its November 1983 issue reported the results of a study made by a geotextile manufacturer in which various geomembranes were evaluated for their puncture and tear resistance, alone and then with the addition of three different grades of geotextile. A laboratory procedure was developed to simulate the effects of equipment moving over the geomembrane. According to the magazine article, "Although there were major differences in the resistance of various membranes, the geotextile fabric offered significant protection from aggregate cutting, puncture and abrasion . . . "[1]

Is a geotextile always necessary for cushioning and protection against puncture and tear? The incorporation of a geotextile with a geomembrane may serve many important purposes, including filtration, soil stability, overburden stabilization, drainage, gas ventilation and so forth. But an appropriately thick liner, which Schlegel Lining Technology defines as 2.0 mm (80 mil) or more, is usually thick enough to resist both high and low speed puncture and resultant tear without the expense of

Continued on page 2.

World's largest uranium mine lines reservoirs with 100 mil HDPE

In the summer of 1983, officials of Key Lake Mining Corporation (KLMC) were faced with the task of having to reline two reservoirs and five monitoring ponds. These are sited adjacent to the mill and tailings deposition area on surficial materials of glacial till, sand and gravel.

Key Lake Mine will eventually be the largest uranium mining/milling complex in the world. Ore is extracted from two discrete deposits by open pit mining methods. The mill is designed to process 780 tons of ore per day using conventional separation and extraction techniques.

The Key Lake Mine site is located 400 miles north of Saskatoon, in Saskatchewan, Canada. Severe winters, featuring temperatures as low as −40°F, are the norm.

The purpose of the reservoirs is to store contaminated water from the open pit and ore stockpile areas. The first reservoir, with a capacity of 240,000 m³, holds mine water and site and stockpile runoff. All runoff from the ore stockpiles, the open pits and the mill is considered contaminated, and is collected and stored in this reservoir. This reservoir also serves as a source of process water for the mill, as no free water is ordinarily introduced into the milling process, other than what is collected by dewatering. This reservoir was lined with 37,000 m² (400,000 ft²) of HDPE material.

The second reservoir holds supernatant water from the tailings area, as well as any other water requiring treatment before it is recycled or discharged to the environment through the monitoring ponds. The capacity of this reservoir is 120,000 m³; it was lined with 20,800 m² (224,000 ft²) of HDPE liner.

The five monitoring ponds with individual capacities of 5,000 m³, hold treated supernatant water from the process plant and are used to test treated water before it is

Continued on page 5.

resistance. As with puncture, however, the right side of the Table gives an evaluation of each system's tear resistance as a whole.

The thickness dependence of both puncture and tear resistance was found to be satisfactorily approximated by a linear function in both cases. The testing also showed that material selection has a significant effect in resisting these failure mechanisms, with HDPE giving the highest values among the materials tested.

Design Option: Dimension Liner Thickness For Earth Settlement

This discussion has not touched on the critical aspect of dimensioning liner thickness to accommodate the almost-inevitable subsoil settlement that can be expected under most impoundments. The puncture and tear resistance of a geomembrane in this situation must certainly be provided for, but far more importantly, the design engineer must ensure that the geomembrane is sufficiently strong and thick to withstand the increase in biaxial tensile loading beyond the design loads, and to alleviate localized stress points. Interestingly enough, a geotextile underlying a geomembrane in these circumstances may be a handicap. This subject will be discussed in the next issue of IN-SITE.

So should the design engineer incorporate a geotextile with a geomembrane for puncture and tear resistance? If a high strength, thick material like SCHLEGEL® sheet is specified, the use of a geotextile for this purpose alone is unnecssary.

FAILED BRINE POND LINER REPLACED WITH SCHLEGEL® SHEET

When a brine pond liner at Warren Petroleum's Mont Belvieu, Texas, petroleum terminal failed, Schlegel Lining Technology was chosen to handle the relining work. Schlegel used 85,500 square meters of 2.5 mm (100 mil) SCHLEGEL sheet, a thick, high density polyethylene (HDPE) liner to complete the project.

Until recently it was common to line the ponds that hold the salt-saturated solution with 1.5m of clay or with thin (less than 2.0 mm/80 mil) membrane liners. But recent studies, showing that clay liners have a tendency to shrink and crack, allowing rapid transport of fluids through them, are moving the industry away from automatic reliance on clay. And the thin liners have shown a susceptibility to puncture and tear, both during their installation and during operation of a facility. Seepage of the saturated salt solution from a brine pond will not only kill vegetation, but can pollute groundwater as well.

The Texas Project.

At the Warren terminal, a variety of petroleum fractions are handled, stored and, ultimately, transported by tank, truck or pipeline to end users.

Salt dome formations are utilized for product storage. The construction of the underground storage caverns is accomplished by injecting fresh water under high pressure into the salt strata. The water dissolves the salt to create a cavity of the required capacity. When the cavern has been hollowed, it is pumped dry, filled with LPG and capped. The salt-laden brine is pumped into holding ponds; as product is required, the brine is forced back into the cavern to displace the petroleum.

SCHLEGEL sheet is highly resistant to both salts and hydrocarbons.

As is true in the United States, HDPE is being used with increasing frequency in Canada for similar applications. New LPG storage beds that underlie Alberta and other parts of western Canada, for example, are creating a demand for brine ponds that are more secure than those constructed in the past. Brine ponds lined with SCHLEGEL sheet are in use for Chevron Canada Resources Limited and Procor Limited, with other installations now in the planning stage.

DENISON MINES $BaRaSO_4$ SETTLING POND

LININGS MUST BE MOOSE- AND PEOPLE-PROOF

DENISON MINES LTD.

DENISON MINES LTD. at Elliot Lake uses a lined pond to settle out $BaRASO_4$ after treatment of tailings decant water before it is discharged to Quirke Lake. This impoundment with plastic dikes to provide a longer residence time is illustrated. Of interest are the moose prints shown on the membrane illustrating that liners should be able to withstand large animal hooves and also not be so slippery that once an animal gets to the water's edge, it cannot climb back up the embankment again.

Details of the DENISON settling pond liner would be available from:

DENISON MINES LTD.
Post Office Box B2600
Elliot Lake, Ontario
Canada P5A 2K2
(705) 848-9111
Dr. J. L. Chakravatti

Of interest here are the steep sides of the banks around the pond and the absence of any sign of the problems experienced by QUIVIRA MINING COMPANY with sloughing embankments and torn membranes. Possible reasons for that are firstly, the more sheltered setting, lower wind velocities (and hence less wave energy), more stable embankments, and absence of the type of rodents that burrow under membranes and gnaw holes though it. In addition, panel seams are down dip rather than along the strike of the walls.

IMPOUNDMENTS AROUND REAGENT TANKS

Increasingly, impoundments are required to be installed around hazardous reagent tanks in case there is a spill or in case the tank develops a leak or fails.

The illustration below shows a berm constructed around a sulfuric acid tank installed at a effluent treatment plant at a Canadian gold mine for pH adjustment. The impoundment has been lined (expensively) with hypalon. The second illustration shows the condition of this liner only 2 years after it was installed--the cement holding the hypalon membrane panels in place is already failing even though no acid has ever spilled.

This example is shown without even mentioning the installation. The important point to stress is that failure of membrane liner systems is all too frequent. In this case, the liner fails because a glue was used that is not compatable with the northern climate or was applied incorrectly. Great care must be taken in selecting both the liner material, the installer, and the impoundment designer. This is an area where failures seem to match successes in number.

LEAK DETECTION BENEATH LINED IMPOUNDMENTS

If a leak occurs in a lined impoundment, by the time it is picked up in the ground water monitoring program, so much water or solution will already have leaked that a major problem may have already been caused requiring an expensive ground water cleanup program.

Early leak detection devices would be a safeguard against this. Two such approaches were identified. One is the use of pressure-vacuum lysimeters that sample fluids in the vadose or unsaturated zone beneath an impoundment. This new system is described by BOND and ROUSE (1985), whose paper is inserted in Chapter 60 on monitoring.

The second is the following paper by Art Lange describing a geophysical leak detection method. More information can be obtained from him at:

ALBIREO LTD.
3798 Marshall Street
Wheat Ridge, CO 80033
(303) 431-0432
Art Lange

Albireo Ltd. is also developing a simple system for leak detection under lined ponds allowing periodic leak surveys. Preliminary tests have proven very effective and by the time this report is distributed, Albireo's patent protection should allow them to demonstrate the new method.

GEOMEMBRANE PRODUCTS

By

J. P. Giroud and R. K. Frobel

Geomembranes are very low permeability membrane liners and barriers used with any geotechnical engineering related material so as to control fluid migrations in a man-made project, structure or system. The term liner applies when a geomembrane is used as an interface or a surface revetment. The term barrier is usually reserved for the cases where the geomembrane is used inside an earth mass. Geomembrane is a generic term which has been proposed to replace many terms such as: synthetic membranes, polymeric membranes, plastic liners, flexible membrane liners, impermeable membranes and impervious sheets. These terms are not appropriate because: (i) synthetic, polymeric and plastic are too restrictive; (ii) geomembranes are not always used as liners; (iii) flexible membrane is redundant; and (iv) no material is absolutely impermeable or impervious. In addition, many users of these materials habitually designate them with trade names, which adds to the terminology confusion. Geomembranes should not be confused with other similar membranes used for such applications as single-ply roofing, floating covers and air supported roofs. Also, geomembranes should not be confused with geotextiles as explained in the foreword.

The types of geomembranes that adhere to the above definition include those composed of polymeric or asphaltic materials,non-reinforced or reinforced with a fabric, made in a factory or applied in situ (ie, at the construction site). Compacted earth linings, incorporating various types of manufactured or natural additives, and hard surface linings such as steel, concrete, gunite, asphaltic concrete and soil cement are not considered as geomembranes.

Geomembranes are used in the construction of potable water reservoirs, distribution canals, municipal and hazardous solid waste landfills, liquid waste lagoons (also called liquid impoundments or surface impoundments), cutoff walls, dam facings, final closure landfill cover, spill containment systems, etc. In these structures, geomembranes serve the primary function of controlling the migration of fluids.

This paper will discuss composition, production, classification and identification of geomembranes.

Composition of Geomembranes

Geomembranes are composed of a very low permeability material, reinforced or not with a fabric.

Very low permeability materials are materials having a very low hydraulic conductivity (also called coefficient of permeability), typically 10^{-14} to 10^{-13} m/s (10^{-12} to 10^{-11} cm/s). (Although, as explained in the foreword, the mechanism by which fluids pass through geomembranes is different from the mechanism by which fluids pass through soils, it is convenient to evaluate permeability of geomembranes using coefficients originally defined for soils.) Among materials having a very low permeability are compounds of which the base product is asphalt and/or a polymer.

Asphalt is obtained either from natural deposits or as a by-product of oil distillation. Blown asphalt, often used to make geomembranes, has been hardened by blowing air through the molten asphalt to raise its softening temperature and decrease its tendency to flow.

Polymers are chemical compounds of high molecular weight. Only synthetic polymers are used to make geomembranes. The most common types of polymers presently used as base products in the manufacture of geomembranes can be classified as follows (symbols in parenthesis are adopted from symbols used by the National Sanitation Foundation (NSF) Joint Committee on Flexible Membrane Liners (FML)):

1. Thermoplastics: Polyvinyl Chloride (PVC); Oil Resistant PVC (PVC-OR); Thermoplastic Nitrile-PVC (TN-PVC); Ethylene Interpolymer Alloy (EIA);

2. Cristalline Thermoplastics: Low Density Polyethylene (LDPE); High Density Polyethylene (HDPE); High Density Polyethylene-Alloy (HDPE-A); Polypropylene; Elasticized Polyolefin;

3. Thermoplastic Elastomers: Chlorinated Polyethylene (CPE); Chlorinated Polyethylene-Alloy (CPE-A); Chlorosulfonated Polyethylene (CSPE), also commonly referred to as "Hypalon"; Thermoplastic Ethylene-Propylene Diene Monomer (T-EPDM);

4. Elastomers: Isoprene - Isobutylene Rubber (IIR), also commonly referred to as Butyl Rubber; Ethylene-Propylene Diene Monomer (EPDM); Polychloroprene (CR), also commonly referred to as "Neoprene"; Epichlorohydrin Rubber (CO).

In addition to the base product, compounds used in geomembranes generally include various additives.

Additives typically compounded with asphalt are fillers, fibers, and elastomers. Fillers are small mineral particles (typically 1 to 200 microns) used to reduce the cost of the asphaltic compound and increase its stiffness, without altering its very low permeability. Examples of particles used as fillers are: limestone, ground calcium carbonate, slate flour, kaolin clay, talc, mica, fly ash, barite, graphite. The weight ratio filler/(filler + asphalt) is usually between 0 and 60%, typically 30%. Fibers, such as asbestos or glass fibers, are sometimes added to asphalt to reinforce it. Elastomers, such as thermoplastic butadiene-styrene-butadiene copolymer, or reclaimed rubber from tires, are sometimes included in asphaltic compounds to improve their mechanical behavior and their resistance to weathering. Typical proportion of elastomer added is between 5 and 15%.

Additives typically compounded with polymers are fillers, fibers, processing aids, plasticizers, carbon black, stabilizers, antioxidants and fungicides. Fillers used with polymers are mineral particles (such as the fillers used with asphalt discussed above), metallic oxides (such as alumina, magnesia, zinc oxide, antimony oxide), ground polymers, saw dust, etc. The weight ratio filler/(filler + polymeric compound) is usually between 0 and 20% for thermoplastics and cristalline thermoplastics, and between 10% and 50% for elastomers and thermoplastic elastomers. Fibers (typically chopped glass, polyester or nylon fibers) are sometimes included in the compound. Inclusion of chopped fibers is delicate and may trigger the formation of pinholes in the geomembrane. Processing aids are used to reinforce or soften the compound during the manufacturing process. Plasticizers are used to impart flexibility to the compound to produce membranes from otherwise stiff compounds such as PVC. Plasticizers may also facilitate the manufacturing process. The weight ratio plasticizer/base product typically varies from 0 to 2% in elastomeric compounds (mostly to facilitate the manufacturing process) to 55% in PVC compounds. Carbon black (typically 1 to 2% of the base product in the case of

thermoplastics and cristalline thermoplastics, and 10% to 45% in the case of elastomers and thermoplastic elastomers) imparts a black color to the compound which retards aging by ultraviolet light from the sun and increases the stiffness of elastomeric compounds. In hot climates, light color geomembranes with a low carbon black content are sometimes used to decrease the risk of degradation of the geomembrane by sun generated heat. Light color geomembranes made with some polymers such as Hypalon may be protected from ultraviolet light by addition of titanium dioxide. Various stabilizers and antioxidants reduce the effect of outdoor aging (by ultraviolet light, ozone, etc) as well as provide compound stability during the manufacturing process. Fungicides prevent fungi and bacteria from attacking the polymer.

Fabric reinforcement is used for one or several of the following reasons: (i) to impart stability to the compound (eg, asphalt, Hypalon) during the manufacturing process; (ii) to provide dimensional stability to compounds that would excessively shrink or expand as a result of change in physical conditions such as temperature; (iii) to increase the strength (tensile, tear, burst, puncture) of the geomembrane to prevent it from being damaged during handling and installation, and to allow it to withstand the design stresses; and (iv) to increase the modulus of the geomembrane in order to decrease its elongation when subjected to stresses. Fabric reinforcement can be of various types depending on the manufacturing process of the geomembrane as discussed below.

In the recent years, knitted fabrics have been introduced to reinforce geomembranes, especially the geomembranes made in a factory by spread coating. However, the most widely used reinforcement fabrics are the nonwovens and the wovens, especially the scrims, as discussed below.

Nonwoven fabrics are used to reinforce geomembranes made in situ and some geomembranes made in a factory by spread coating. Nonwoven fabrics can also be bonded to geomembranes by the calendering method. The nonwoven fabrics used to manufacture geomembranes are usually needlepunched, with a mass per unit area typically ranging between 200 and 600 g/m^2 (6 to 18 oz./sq. yd.) (see the article entitled "Geotextile Products", by J. P. Giroud and R. G. Carroll, Jr, published in the first issue of the Geotechnical Fabrics Report, Summer 1983).

Woven fabrics are used to reinforce some spread coated and some calendered geomembranes. The type of woven fabric generally used to reinforce calendered geo-

membranes is a scrim. A scrim is a type of open weave fabric with a low mass per unit area (ie, a "lightweight" fabric). A plain weave scrim is one in which each filling (cross-machine direction) yarn passes successively over and under each warp (machine direction) yarn, alternating each row. A leno weave scrim is one in which warp yarns are arranged in pairs and twisted around each other between picks of filling yarn (each warp yarn passing successively over and under each filling yarn). This type of weave imparts strength and prevents slippage in an open weave fabric. In some scrims, one half of the filling yarns are over the warp yarns, the other half being under the warp yarns (ie, yarns in one direction do not pass successively over and under yarns in the other direction). These scrims have no stability. They must be dipped into a liquid that bonds yarns together. Sometimes scrims are made thinner by calendering them prior to calendering the compound. A scrim is characterized by its count and the linear density of its yarns. The count is the number of yarns per unit width (in meter, centimeter, or inch) in each direction (warp and filling). The linear density of a yarn is its mass per unit length. Units for linear density are kg/m or, more conveniently, tex which is 10^{-6} kg/m (ie, g/km or mg/m). The traditional unit for linear density is the denier (one tex = 9 deniers, ie 1000 deniers = 111 tex). Examples of scrims available in the United States are:

- 630 x 315/m (16 x 8/inch), 14 tex warp/28 tex filling (125 deniers warp/250 deniers filling), leno weave, often referred to as 8 x 8, 250;
- 480 x 240/m (12 x 6/inch), 55 tex warp/111 tex filling (500 deniers warp/1000 deniers filling), leno weave, often referred to as 6 x 6, 1000;
- 4 x 4/cm (10 x 10/inch), 111 tex (1000 deniers), plain weave, often referred to as 10 x 10, 1000.

Examples of scrims available in Europe are:

- 4 x 4/cm (10 x 10/inch), 28 tex (250 deniers);
- 2 x 2/cm (5 x 5/inch), 111 tex (1000 deniers);
- 3 x 3/cm (7.5 x 7.5/inch), 111 tex (1000 deniers).

The mass per unit area of a scrim is derived by multiplying the count by the linear density in both directions and adding. Example: the mass per unit area of a 480 x 240/m, 55 tex warp/111 tex filling is $480 \times 55 \times 10^{-6} + 240 \times 111 \times 10^{-6} = 0.053$ kg/m^2 = 53 g/m^2 (1.6 oz./sq. yd.)

Although all reinforced geomembranes presently available are, to the best of our knowledge, reinforced with fabrics, it is possible that, in the future, other forms of reinforcement will be available.

Production of Geomembranes

Most geomembranes are made in a plant using one of the following manufacturing processes: (i) extrusion, (ii) spread coating, or (iii) calendering.

Extrusion process is a method whereby a molten polymer, usually of the polyolefin family (such as polyethylene, polypropylene), is extruded into a non-reinforced sheet. Immediately after extrusion, when the sheet is still warm, it can be laminated with a fabric, through light calendering; the geomembrane thus produced is reinforced.

Spread coating process usually consists in coating a fabric (woven, nonwoven, knit) by spreading a polymer or asphalt compound on it. The geomembranes thus produced are therefore reinforced. Non-reinforced geomembranes can be made by spreading a polymer on a sheet of paper which is removed and discarded at the end of the manufacturing process.

Calendering is the most frequently used manufacturing process. A calendered non-reinforced geomembrane is usually a single sheet of compound made by passing a heated polymeric compound through a series of heated rollers (calender). Some calendered non-reinforced geomembranes are produced by simultaneously running two sheets of compound through heated rollers. The purpose of this process is to minimize the risk of having a pinhole through the entire thickness of the geomembrane. Pinholes are small holes that can exist in a sheet of compound as a result of grit or other cause during the manufacturing process. Calendered reinforced geomembranes are produced by simultaneously running sheets of compound and scrims through heated rollers. A three-ply calendered reinforced geomembrane is made of the following layers: compound/scrim/compound. A five-ply calendered reinforced geomembrane is made of the following layers: compound/scrim/compound/scrim/compound. The polymeric compound, when heated and pressed by the rollers, tends to flow through the openings of the scrim, thus providing adhesion between the sheets of compound located on both sides of the scrim. This adhesive mechanism is commonly known as "strike-through".

the resulting membrane is reinforced (however, at fabric overlaps, the reinforcement is continuous only if the reinforcing fabric is sewn). The sprayed material must penetrate the fabric and thus adhere to it after curing to provide a consistent reinforced spray-applied geomembrane.

Classification of Geomembranes

Based on the information discussed above, geomembranes can be classified according to production process and reinforcement:

1. Made in situ, non-reinforced geomembranes are made by spraying or otherwise placing a hot or cold viscous material directly onto the surface to be lined (earth, concrete, etc). The non-reinforced geomembranes made by spraying are called "sprayed-on (or spray-applied, or sprayed in situ) non-reinforced geomembranes". Typical materials used are based on asphalt, asphalt-elastomer compound, or polymers such as polyurethane. Due to the spray application, the final thickness of such geomembranes is not easy to control and may vary significantly from one location to another. Typically, required thicknesses range between 3 and 7.5 mm (120 and 300 mils).

2. Made in situ, reinforced geomembranes are made by spraying or otherwise placing a hot or cold viscous material onto a fabric. The reinforced geomembranes made by spraying are called "sprayed-on (or spray-applied, or sprayed in situ) reinforced geomembranes". Typical materials used are the same as for the made in situ non-reinforced geomembranes described above. Typical fabrics used are the needlepunched nonwoven geotextiles because they can absorb viscous materials. As discussed above, the final thickness of such geomembranes is not easy to control. Typically, required thicknesses range between 3 and 7.5 mm (120 and 300 mils).

3. Manufactured, non-reinforced geomembranes are made in a plant by extrusion or calendering of a polymeric compound, without any fabric reinforcement, or by spreading a polymer on a sheet of paper removed at the end of the manufacturing process. Typical thicknesses range from 0.25 to 4 mm (10 to 160 mils) for geomembranes made by extrusion and 0.25 to 2 mm (10 to 80 mils) for geomembranes made by calendering. Typical roll width for geomembranes made by extru-

sion is 5 to 10 m (16 to 33 ft), although some are narrower. Typical roll width for geomembranes made by calendering is 1.5 m (5 ft), with some manufacturers producing 1.8 to 2.4 m (6 to 8 ft) wide rolls.

4. Manufactured, reinforced geomembranes are made in a plant, usually by spread coating or calendering. In spread-coated geomembranes, the reinforcing fabric (woven or nonwoven) is impregnated and coated on one or both sides with the compound, either polymeric or asphaltic. In calendered reinforced geomembranes, the reinforcing fabric is usually a scrim. Calendered geomembranes are always made with polymeric compounds and are usually made up of three plies: compound/scrim/compound. Sometimes they are made of five plies: compound/scrim/compound/scrim/compound. Geomembranes with additional plies can be made on a custom basis. Typical thicknesses of asphaltic spread-coated geomembranes are 3 to 10 mm (1/8 to 3/8 inch). Typical thicknesses for polymeric spread-coated and three-ply calendered geomembranes are 0.75 to 1.5 mm (30 to 60 mils). Typical thicknesses for five-ply calendered geomembranes are 1 to 1.5 mm (40 to 60 mils). Some two-ply reinforced geomembranes are manufactured by extrusion of a non-reinforced sheet, followed by light calendering with a fabric.

5. Manufactured, reinforced geomembranes laminated with a fabric are made by calendering a manufactured geomembrane (usually a non-reinforced geomembrane previously made by calendering) with a fabric (usually a nonwoven) which remains apparent on one face of the final product.

Identification of Geomembranes

An abbreviated system for identifying geomembranes consists of providing the generic name (or initials) of the base product, followed by the letter R if the geomembrane is reinforced. Examples: a PVC geomembrane; a CPE-R geomembrane. (Note: the term "supported", sometimes used for "reinforced", is not recommended because it may create a confusion with the "supporting" soil or geotextile on which the geomembrane is resting.)

A comprehensive system for identifying geomembranes consists of listing: (i) the production process, only if the geomembrane is made in situ (if the geomembrane is made

in a plant, this does not need to be mentioned); (ii) generic name of the base product (ie, asphalt or type of polymer); (iii) thickness (since the significant thickness is the thickness of the low permeability compound, the thickness to be indicated is the total thickness of geomembranes types 1 through 4 (except the case of fabrics coated one side only), while it is the thickness excluding the associated fabric in the case of geomembranes type 5); (iv) reinforcing fabric, if any (the type of fabric and the type of polymer, such as polyester or nylon, should be given; if the fabric is a woven (including scrim) or a knit, count and linear density of yarns, and the type of weave or knit should be given; if the fabric is a nonwoven, the mass per unit area should be given). (Note: for fabric types see the article entitled "Geotextile Products", by J. P. Giroud and R. G. Carroll, Jr, published in the first issue of the Geotechnical Fabrics Report, Summer 1983.)

Examples of geomembrane identification are as follows:

- sprayed in situ, asphalt-neoprene compound, 3 mm (120 mils) in thickness, non-reinforced;
- sprayed in situ, asphalt, 2.5 mm (100 mils) in thickness, reinforced with a polypropylene spunbonded needlepunched nonwoven, 370 g/m^2 (11 oz./sq. yd.);
- polyvinyl chloride (PVC), 0.75 mm (30 mils) in thickness, non-reinforced;
- asphalt-elastomer compound, 3.5 mm (140 mils) in thickness, reinforced with a polyester staple fiber needlepunched nonwoven, 230 g/m^2 (7 oz./sq. yd.);
- chlorinated polyethylene (CPE), 0.75 mm (30 mils) in thickness, reinforced with 4 x 4/cm (10 x 10/inch), 111 tex (1000 deniers) plain weave polyester scrim;
- chlorosulfonated polyethylene (CSPE), 0.9 mm (36 mils) in thickness, reinforced with 480 x 240/m (12 x 6/inch), 55 tex warp/111 tex filling (500 deniers warp/1000 deniers filling) leno weave polyester scrim (Note: The scrim can more simply be described by: 240 x 240/m (6 x 6/inch), 111 tex (1000 deniers) leno weave);
- chlorosulfonated polyethylene (CSPE), 1.15 mm (45 mils) in thickness, five-ply, reinforced with two plies of 315 x 315/m (8 x 8/inch), 28 tex (250 deniers) leno weave polyester scrims;
- butyl rubber, 1.5 mm (60 mils) in thickness, laminated with a polypropylene spunbonded heatbonded nonwoven fabric, 270 g/m^2 (8 oz./sq. yd.).

The above identifying characteristics are only minimum descriptors. Detailed information on physical and mechanical properties as well as chemical resistance and compatibility with hot, cold or wet environments is needed before a geomembrane is determined to be suitable for a specified application. All pertinent characteristics and properties must be considered before final selection of a geomembrane is made.

Conclusion

The information presented herein should provide the reader with a basic knowledge of the types of geomembranes in use today. This article has purposely avoided such subjects as geomembrane polymer technology, physical and mechanical test procedures, design methodology, and installation technology. These are separate topics that are addressed in numerous technical journal articles and books available through libraries throughout the world. A wealth of information is also available from geomembrane manufacturers and marketing groups. Those readers who wish to gain first hand knowledge on geomembranes should attend the International Conference on Geomembranes to be held in Denver, Colorado, 20-24 June 1984. SELECTION CRITERIA FOR THE USE OF SYNTHETIC MEMBRANE LINERS IN THE CONTAINMENT OF HAZARDOUS WASTES

BY

RICHARD K. SCHMIDT, Ph.D.
PAUL W. BARKER

PRESENTED TO:
54TH ANNUAL WATER POLLUTION CONTROL
FEDERATION CONFERENCE
OCTOBER, 1981

3623

INTRODUCTION

Recent studies have revealed the existence of over 70,000 water impoundments and landfill sites, many which contain hazardous and toxic material capable of contaminating ground water supplies. The majority of these sites fail to provide properly designed containment security of their contents. The passage of the Resources Recovery Act (RCRA) requires more stringent engineering design of the containment aspects of existing and future disposal sites.

There are numerous materials which can be considered for use as linings for hazardous waste impoundments. Among them are clay and bentonite, cement stabilized sand, and flexible membrane liners.

Clay layers, often 2' or 3' thick have been used extensively but recent work and study has shown that certain solutions, particularly alkaline solutions can seriously affect clay's use as a permanent lining material.[1]

The use of thinner layers of betonite which swells in contact with water to form a relatively impermeable layer can also be limited in certain chemical environments.

Cement stabilized sand is not suitable when acidic conditions are experienced.

As far as flexible membranes are concerned there is a wide range of materials available all of which can find application with greater or lesser success in hazardous waste environments. It should be realized that in civil engineering, a membrane is defined as a thin impermeable sheet which may be flexible or rigid and used to separate two environments. Such a membrane normally only has strength in two directions and requires support to resist load normal to its plane. One of its principal properties is impermeability - particularly important in the containment of hazardous waste.

Because of their cost effectiveness, synthetic membrane liners are gaining increasing engineering acceptance as the containment material of choice. The intent of this paper is to review the history of flexible membrane liners, discuss the physical and chemical characteristics of the more widely used materials and to present the design engineer with a step by step approach to be used in the application and selection of the correct liner.

HISTORY OF FLEXIBLE MEMBRANE LINERS

At this point it would be appropriate to review the history of the development of the use of flexible membranes over the years. Much of the early lining work was carried out at the U. S. Department of Agriculture's Research Station in Utah. Here in 1948 the first reinforced butyl rubber lining was installed in an irrigation canal.

Other materials such as PVC and low density polyethylene were also studied and in 1955 the first butyl rubber pond liner was installed. In the early sixties in Europe there was considerable interest by the rubber producing oil companies to develop the market for butyl rubber in particular and a method of vulcanizing relatively narrow - 4 feet wide - sheets of rubber was developed. At the same time wider widths of low density polyethylene became available although the jointing method remained relatively unsophisticated involving the use of soft, sticky tapes with relatively low shear strengths. Subsequently more sophisticated mechanical clamp systems for sealing low density polyethylene were developed.

Plasticised PVC in sheet form also began to be used in the early sixties. In this case 4' or 5' wide calendered sheets were welded together in a prefabricators factory usually by means of high frequency welding machines. The large panels were joined together on site using special adhesive.

Also in the U.S.A., chlorosulphonated polyethylene, commonly known as Hypalon, was developed in the early fifties and was first used in a reinforced form for a floating cover application in 1972. During the late seventies chlorinated polyethylene, CPE, sheeting was introduced and as with Hypalon, relatively narrow widths had to be prefabricated in a factory prior to site installation. Yet another lining material known as 3110, a polyolefin was available for a few years from 1975-79.

Blends of nitrile rubber and PVC in sheet form were developed in the late seventies for oil resistant lining applications whilst in the mid seventies, thick HDPE, pure high density polyethylene was used for the first time as a lining material.

The history is summarized in Figure 1.

```

From this discussion, we can see that synthetic membrane liners have been in extensive use for over 30 years and that in time, better materials have been developed to meet the demands of the marketplace. It is believed that the most recent generation of lining materials offers the designer the type of product required for the permanent encapsulation of hazardous waste facilities.

MEMBRANE PROPERTIES

To be effective, flexible membrane liners should have a combination of the following properties:

1. Strength
2. Toughness and flexibility
3. Durability
4. Chemical resistance
5. Effective jointing system

Strength involves the tensile properties at various elongations - that is to say the stress strain characteristics of the material.

Toughness involves the tear and puncture resistance of the material while flexibility is a desirable feature both during installation and in service.

Durability involves resistance of the material to environmental factors and clearly long term durability is an important consideration in most lining applications.

Chemical resistance is primarily concerned with the membrane's ability to withstand exposure to a wide range of chemically aggressive environments without deterioration or loss of properties.

An effective jointing system is of course the "link in the chain". Ideally the jointing system should involve true welding that creates a perfectly homogeneous fusion of the two edges, achieved as necessary by the introduction of a material of identical nature to the lining membrane. Systems based on adhesives have characteristics that could produce variable results and are therefore not ideal for more critical applications.

Let us now focus in more detail on the physical properties which may be used as indicators in the evaluation of various membranes. Table 1 presents physical properties which are typically evaluated.

TABLE 1

PHYSICAL PROPERTIES

Tensile Strength - at yield and break	Water Absorption
Elongation - at yield and break	Volatiles
Tear Resistance	Low Temperature Impact
Puncture Resistance	Ozone Resistance
Dimensional Stability	Abrasion Resistance
Permeability	

The tensile strength of lining materials is normally measured at yield and at break. Standard samples are cut and pulled at a constant speed on sophisticated tensometers and readings taken, units being in lbs/inch. The same equipment is used to measure elongation at yield and break; units are given as a % of the original. Tear resistance involves pulling a standard tear sample and measuring the force in pounds required to tear the material. Puncture resistance measures the resistance of the material to the application of the standard pointed steel piece and units are measured in lbs. These tests measure the strength and toughness of various materials.

Dimensional Stability measures the % change in dimensions in a standard piece after heating the sample for 15 minutes at 212°F. Permeability of a membrane to moisture vapor is measured in $gm/m^2/24$ hrs.

A water absorption test is carried out which measures the % water absorbed after two weeks immersion at 50°C. The Volatile's test measures % of loss at 105°C - an important test to determine the amount of volatile constituent in the compound which could be affected by loss over the years.

Low temperature impact is a test carried out to determine the temperature at which the lining material becomes unable to resist impact and ozone resistance is measured to determine the material's resistance to this active gas present in the atmosphere. No cracks should be visible in the membrane after 7 days exposure at 20% elongation at 104°F and 100 pphm of ozone. Abrasion Resistance is often measured and this property can be important in the abrasive environments. These tests provide guides to a material's ability to withstand long term weathering.

At this point it would be interesting to carry out some comparisions of the physical properties of the most frequently used lining materials.

Figure 2 shows comparative data on 30 mil unsupported materials namely PVC, CPE, Hypalon, Butyl, and HDPE. The diagram illustrates the high tensile strength of HDPE when compared to other polymer materials.

Because some basic polymers have low tensile strengths, flexible membrane liners made from this material must be reinforced with a fabric scrim to obtain additional strength. Scrims are open weave mesh fabrics which are laminated between layers of sheeting to produce a single sheet. Materials containing a fabric are given the designation, reinforced, because of the scrim reinforcement they contain.

Figure 3 shows the effect of scrim addition to two common reinforced products, Hypalon and CPE. PVC, Butyl and HDPE are unreinforced products. Figure 3 also presents information on the elongation characteristics of these materials. An unreinforced material, such as HDPE will typically yield at 10% of its ultimate tensile strength but will continue to stretch, breaking at an ultimate elongation of 700%.

FIGURE 2

The strength of reinforced materials comes from the scrim. Once the scrim fails, typically occurring at about 15% of the breaking strength, the strength properties revert back to the relatively low physical properties of the unreinforced polymers compound. These materials also tend to have lower elongation characteristics.

Figure 4 shows data on puncture resistance. The data is more closely correlated for all materials since this property is usually a function of thickness.

A study of all physical properties of lining materials is an important phase of the evaluation procedure. However, it is also important to be able to know how these properties change on exposure both to the weather and to particular environments. Accelerated heat aging tests have been carried out onmany lining materials and it is possible to extrapolate from this test data to determine an ultimate life, heat of course being one of the main factors causing deterioration of membranes in service. Ideally test data obtained from samples of lining material which has been exposed to certain environments for many years gives the best indication of longevity. Table 2 summarizes the desired properties of flexible membrane liners and the test which can be used to evaluate them.

FIGURE 4

CHEMICAL COMPATIBILITY

Turning now from physical properties, we must now consider the question of chemical resistance. There are of course a wide range of chemicals to which the lining material can be exposed, particularly in hazardous waste applications. Therefore, the lining material chosen must have a degree of chemical resistance appropriate to the type of installation envisaged. The main types of chemical include acids, alkalis, aromatic solvents, and oils.

Most membranes currently available are able to withstand acids and alkalis but resistance to solvents and oils is limited, the most resistant lining materials being PVC Nitrile blends and HDPE. It must be realized of course, that any waste or effluent stream can contain a wide range of chemicals and different combinations can have different effects particularly in fluctuating temperature situations. If at all possible it is always better to carry out immersion tests in actual solutions of effluent in order to determine possible effects.

For most applications, immersing a sample of the material into the waste liquid for approximately 30 days will give a good indication of the material compatability. This test can be easily run in the laboratory and should as closely as possible, approximate field conditions. This is particularly true if temperature extremes are expected.

After 30 days, the samples are removed from the immersion tests, weighed to determine if the waste material has been absorbed, and then a series of physical tests are run to determine if there has been any change in the physical characteristics of the material. If deterioration has occurred, this may indicate that the material is not suitable for the intended application. In cases where an extreme hazard exists, the tests may be run for an extended period in time. Also, there are methods available to run accelerated aging tests on materials, however, these are quite expensive. For most applications the 30 day laboratory compatability test will suffice. Figure 5 presents tensile strength data for various materials after immersion in landfill leachate for 8 and 19 months. This is typical of data which can be obtained from immersion studies.

SEAMING

Potentially the weakest link in any liner system is the joining system. The type and number of joints influence the degree of safety achieved in a particular application.

Most lining materials are manufactured in roll goods whose width is only 4 - 5 ft. Since it is uneconomical to field seam such narrow widths, larger panels of material are fabricated in the factory to reduce field installation costs.

FIGURE 5

RETENTION OF TENSILE STRENGTH OF MEMBRANE LINERS AFTER IMMERSION IN LANDFILL LEACHATE FOR 8 AND 19 MONTHS.

REF: EPA REPORT
SW 870

Thus, there are two types of seams, factory and field. The only commercially available material which contains no factory seams is HDPE. Manufacturing techniques allow this material to be fabricated in widths exceeding 20 ft., thus, the sheets are taken directly to the field for installation.

The types of seaming methods currently in use are as follows:

1. Solvent/Adhesive
2. Thermal
3. Dielectric
4. Homogeneous Welding

These are listed in ascending order in terms of cost. Typically PVC, Butyl, Hypalon, and CPE can be bonded using solvent/adhesive, thermal or dielectric means. Of the three, the dielectric method provides the best seam but it is the most expensive and is also not conducive to field installation. As a result, many fabricators use dielectric methods for factory seams and use either solvent/adhesive or thermal means for field seaming.

HDPE uses the homogeneous welding technique for field seams. This involves the extrusion of a bead of parent material directly onto the lapped edges which if properly applied develop a bond as strong as the parent material. The technique is similar to the welding of steel.

For greatest security, the seaming method should be capable of producing a bond as strong as the base material. Seams should be tested in both shear and peel to ensure their integrity.

SELECTION CRITERIA

Up until now we have discussed various properties of available membranes. Since there are significant differences in chemical and physical properties, the engineer is faced with the task of applying the correct membrane to each application. To begin with, there are four basic criteria which should be evaluated, these are:

1. Site planning considerations
2. Degree of hazard
3. Service time
4. Membrane selection

By far the most important selection element is site planning considerations. Table 3 list various factors which should be considered when designing a containment facility.

TABLE 3

FACTORS TO BE CONSIDERED IN THE SITE PLANNING CONSTRUCTION PROCESS

1. Characteristics of the waste to be impounded
2. Characteristics (type and texture) of "in situ" soil materials
3. Subgrade characteristics - soil borings
4. Desired characteristics of bottom and side surfaces
5. Location of bedrock
6. Stability of materials
7. Drainage considerations
8. Impoundment dimensions
9. Wind direction and velocity
10. Ambient temperature
11. Gas venting
12. Local vegetation
13. Floor considerations
14. Berm width requirements
15. Inflow/outflow/overflow conveyances
16. Monitoring/leak detection systems
17. Cover material availability/characteristics
18. Proximity to major waste generators
19. Proximity to residential and commercial areas
20. Coupon testing and evaluation, if applicable
21. Weed control

The geotechnical aspects of site design are extremely critical. It should be emphasized that while flexible membrane liners offer a high strength/thickness ratio, they should not be considered structural members. Numerous failures have occurred as a result of poor engineering design of the containment system. The base and side slopes of the pond should be well stabilized to assure there will be no slope failure or significant differential settling. Movement of the underlying base can create inordinate stresses in the membrane which could result in ultimate failure. One of the important properties of membranes is that they will elongate and therefore, can accommodate some movement, however, the design engineer should try to minimize this. The subbase should also be properly graded with no rocks or penetrating objects which could puncture the material.

The subsurface conditions below the pond bottom should also be considered. A high or fluctuating water table could create undue pressure on the membrane. Additionally, if gas is present below the membrane it can be forced upward by the water table and if not properly vented can cause the membrane to float.

Environmental factors are also key to selection criteria. Such factors as light and ozone intensity, can affect the membrane if it is installed exposed. Exposed membranes normally contain carbon black to protect against the effect of exposure to weather.

Temperature both ambient as well as the temperature of the contained waste water also plays a critical factor. Most membranes lose strength with increasing temperature.

Degree of hazard will also influence selection criteria. Put simply, containment of a pure water supply does not present the same degree of hazard as containment of a toxic and hazardous waste, although the former may be as equally important due to water conservation requirements.

Service time should also be considered. There are many applications which only require service for one or two years. The membrane for this service could be of a lower quality than one required for twenty years service.

Having decided upon the type of liner, the engineer must still determine the design thickness. This will be affected by subgrade preparation, installation method, and future maintenance requirements. For example, for a properly prepared subgrade in a pond which will be completely full after installation a relatively thin film membrane could be selected in the order of magnitude of 30 to 35 mil. However, if the membrane is to be installed over a rougher subsurface or will be drained and cleaned by mechanical means at some later date the application may require a thicker membrane.

One of the most effective methods of analyzing the effects of thickness was recently developed by the U. S. Department of Interior.(2) It involves placement of the membrane in a pressurized vessel over a sample of the actual subbase. The vessel is then pressurized at various levels to determine the failure point of membranes over different subbases. This method is particularly valuable for deep ponds where large hydraulic heads are anticipated. It does not give a direct correlation to tire loads and or track loads which could be created during the installation process or subsequent cleaning process. The engineer can calculate these loads and relate them back to thickness.

FLEXIBLE MEMBRANE SUPPLIERS

Once all of the economic and technical evaluations have been completed, a supplier will ultimately be selected to supply and install the material. Figure 6 diagramatically shows a breakdown of the flexible membrane liner industry.

The process begins with raw material production which is typically done by the major chemical companies. Using basic polymer components, the raw materials are then compounded into various chemical compounds. It is at this step that the formulations are "customized" for specific applications.

After compounding, the materials are manufactured into sheets by either calendering or extrusion. Sheet goods are then fabricated into larger panels which are then shipped to the field for installation.

FIGURE 6

FLEXIBLE MEMBRANE LINER INDUSTRY

There are some suppliers who are fully integrated from the compounding of the raw material through to installation. Others are merely installers of fabricated panels. If warranty and security are important, the integration of the supplier may become an important consideration.

ECONOMICS

Last but not least is the estimated cost of the material selected. Figure 7 gives budget estimate installed costs for the liner materials described in this paper as well as the range of thicknesses normally available. PVC is usually the most economical material although it must be covered due to its generally poor long term weatherability. HDPE, Hypalon and CPE are normally considered for most hazardous waste facilities with selection dependent on the specific nature of the application. HDPE offers the broadest range of thickness availability while Butyl is usually the most expensive.

It should be emphasized that the overall cost/performance ratio of a particular liner material should be evaluated prior to final selection.

SUMMARY

The use of flexible membrane liners for the containment of hazardous wastes is very cost effective. However, careful engineering evaluations of a material's chemical and physical properties, joining techniques and careful supplier selections are required. By following the steps outlined in this paper, the engineer can assure himself of selecting and applying the correct membrane for each application.

LEAK-DETECTION IN DAMS OF RESERVOIRS AND TAILINGS PONDS BY THE SELF-POTENTIAL METHOD

The problem of leaky dams and tailings ponds is one that is becoming of increasing concern these days. In the case of water reservoirs the danger lies in possible dam failure or water loss; in the case of tailings, we have a potential problem of contamination of streams or groundwater by waste water. There exists a powerful geophysical method for locating such leaks--a method that also happens to be quite economical. I am speaking of the self-potential method (Figure 1), devised during the 1800's for the purpose of mapping mineral deposits, and--more recently--applied to the solving of groundwater and engineering problems. It is the method commonly used to find leaks in pipelines. I employed the technique in the search for geothermal fluids for AMAX since 1977, and, with my present firm ALBIREO, have been applying SP to mineral, groundwater, and petroleum exploration, as well as to leakage problems in reservoirs. Self potential is a passive electrical technique that maps distortions of the natural d.c. electric field in the ground, arising from natural and artificial conductors, movement of fluids, and other causes. Here is an example of the SP response due to a cylinder of powdered pyrite as modeled in our (Figure 2). The presence of oxidation/reduction reactions going on above and below the groundwater level sets up a natural batteries that generate local electrical circuits in the surrounding medium. The net result is typically a sharp negative anomaly over the conductor. Here is a classic example of an SP negative anomaly over an auriferous sulfide deposit in Turkey (Figure 3).

Another laboratory experiment demonstrates the effect of moving groundwater on the surface potential (Figure 4). Streaming potentials arise from the stripping of ions across the Helmholtz double layer between the solid/liquid boundaries of a porous or fissured material. In this case we are dealing with a solution of potassium nitrate in quartz sand. The negative ions customarily adhere to the sand, while the positives move with the fluid: the end result is a potential gradient along the flowpath, with the more positive response around the point of discharge. In the natural environment this process gives rise to negative voltages over areas of recharge and positives in the discharge areas, such as valleys. Here is an example from Kansas, obtained during a petroleum SP survey, where a potential difference of about 35mV

correlated closely with the inverse of the terrain (Figure 5). Another example is from the Caucasus (Figure 6). Groundwater anomalies exceeding 2 volts can be found over volcanic craters in areas of high precipitation, such as Alaska and Hawaii.

At this point let's explain briefly how SP readings are taken. We employ non-polarizing electrodes--either copper/copper- sulfate or lead/lead-chloride types--inserted into shallow holes in the ground and connected by a long cable and high-impedance digital meter (Figure 7). One electrode serves as a base, while the other is a roving element, which we continually move outward along a line. Voltage readings are made at intervals, anywhere from 10 or 20ft (in the case of dam work) up to 100 or 200 meters for geothermal prospecting. Data are then subjected to a number of corrections (for electrode drift, etc.) and profiles and contour maps are plotted to depict local anomalies. The field procedure is carried out by two persons, and preliminary data processing can be done at the end of each day. Final analysis, plotting and interpretation are done later at our computer.

That positive SP responses come about over fluid discharges can be seen in these examples: 1) a karst rise of groundwater from carbonate solution conduits into overlying alluvium (Figure 8); a pair of convection cells driven by hot lava in a dike in Hawaii (Figure 9), and the discharge of Red Hills hot spring in Utah, correlated with the temperature profile (Figure 10). The Soviets have published numerous cases of SP response over dams and reservoirs, and I show several cases here. Monitoring is done across either face of an earth-fill dam, around the shoreline of the reservoir, as well as across the water surface. Here is an example of a reservoir that was elevated after a long period of sedimentation (Figure 11). SP measured along the water surface showed a relatively flat response over the stable former lake; however, as the lake level encroached on new ground, negative SP anomalies were seen. Flowmeter measurements confirmed that water was leaking into the underlying rock and producing eddies. Corresponding positive anomalies were observed around the base of the dam. Another case of a high dam in Armenia 180m wide shows the results of SP surveys across the dam face at two different water levels (Figure 12). The contours of SP response reveal a depression surface shifting in orientation from the east to the southwest as the water rose. The localized negative anomalies represent concentrated zones of downward infiltration later found to result from inhomogeneities within the fill. The result was considerable frontal and roundabout seepage, with consequent water losses. Measures were then taken to control the leakage.

I am permitted to show examples of SP profiles over two leaky reservoirs on a livestock ranch in Wyoming. In the first case the dam had a head of about 15 feet, and observed seepage varied from that of muddy ground to flowing water (up to 10gpm, estimated) (Figure 13). We devised a rough seepage index ranging from 0 for dry ground to 10 for fountains (Table 1). Five represents very muddy ground, and at a value of 6 or 7 water is discharging as a small stream. After sampling the ground and noting the seepage at 20ft intervals, SP measurements were made at the same sites along profiles at the dam base and 10ft upslope. Both showed a strong correlation between the apparent seepage and positive SP

response. One evident exception likely represents seepage that is not obvious at the surface. We had hoped to be able to run a profile along the waters edge of the reservoir to look for corresponding negative SP features indicating points of infiltration; however, excessive metal junk used to prevent wave erosion made the attempt futile. As I mentioned earlier, SP does respond strongly to the presence of conductors.

In a second dam--this one over 1500ft long--a similar correlation was found (Figure 14). In this case sharp negative anomalies appeared in the vicinity of metal pipes serving as drains. SP negative trends beyond the ends of the dam correspond to rising ground, and reflect normal groundwater movement beyond the influence of the dam itself. Again in this case we couldn't survey along the water's edge because of the abundance of automobiles parked in the water.

The SP techniques that I have illustrated can be applied to any kind of impondment, particularly that of tailings. While there can be a decline in SP response with lowered pH of the contained fluids, we can still expect to see substantial leakage, particularly within porous fill. Resistivity methods, on the other hand, which map only the presence of the fluid rather than its movement, would probably fail in the case where the fluid or the fill was very conductive. In any event, SP anomalies can be reinforced by other geophysical tools, such as thermal, seismic, flowmeter and electrical surveys;, however, these are more expensive and time-consuming. A typical SP survey over a dam such as I have shown might require one or two days in the field plus the subsequent data processing. Self potential should be considered as the primary tool to employ, to be followed up by another method directed at the leaks identified by the SP survey.

MONITORING GROUNDWATER

To determine whether impoundments are achieving what they were installed to do, namely to keep contaminants from escaping to the environment, it is necessary to monitor groundwater around many tailings and effluent ponds. Ground water quality protection is currently becoming one of the main focal points of the USEPA and also of some state regulatory agencies. Groundwater monitoring is required in most operator permits for new hydrometallurgical mineral processing installations in the U.S.A. and is likely to be required increasingly for non-U.S.A. operations in the near future. When RCRA regulations are finally formulated for solid waste disposal in the mining industry, the need for monitoring is expected to increase considerably, especially if the RCRA

ENVIRONMENTAL MONITORING FOR REGULATORY COMPLIANCE AND OPERATIONAL CONTROL

INTRODUCTION

Environmental monitoring is currently required under a number of various environmental regulations. All too often, such environmental monitoring is regarded by the operational personnel as a necessary evil, to be conducted at the least possible cost, with little or no in-house use of the data or any significant effort at quality control of the data other than that required by the regulations.

Contrary to this common approach, environmental monitoring can be highly useful, not only as a protection against being blamed for natural environmental degradation resulting from mineralized ground or from past operations, but such environmental monitoring can also be highly useful in operational controls of milling and leaching operations. The following discussions will center on the types of environmental monitoring which must and should be conducted, and uses of such operational monitoring data in control of the facility.

APPLICABLE REGULATIONS

Environmental monitoring of various media (air, receiving water, effluent, ground water, etc.) is required by a number of Federal regulations and state counterparts. Some of the more critical regulatons are discussed below.

Waste water discharges are permitted under a National Pollutant Discharge Elimination System (NPDES) permit issued under the Clean Water Act. Such permits require effluent monitoring and frequently specify receiving water monitoring, to assure compliance with stream standards. Extensive ground water monitoring is required by the Resource Conservation and Recovery Act (RCRA), for solid waste or hazardous waste facilities. At present, mining operations are exempt from RCRA; however, this happy condition is likely of short-term duration. Many states have existing ground water regulations which mandate monitoring. Stack and ambient air sampling is required under the Clean Air Act. Preparation of an environmental impact statement will often require preoperational air, stream and ground-water sampling. Facilities operating under an NRC Source Materials License will similarly require air and water sampling.

TYPES OF MONITORING

Monitoring types can be subdivided under a number of categories, such as chronologic (time sequence) or media monitoring which centers on the type of material (air, effluent, or receiving water) being sampled.

Chronological Monitoring

Monitoring operations follow a logical chronological sequence, beginning with preoperational monitoring, going through monitoring conducted during the life of the operation, and culminating with monitoring during reclamation and post-closure periods.

The preoperational monitoring is required by a number of environmental regulations, to define baseline conditions which exist prior to the onset of project activities. Generally, such preoperational monitoring is considered to extend over at least a one-year period of time, to provide information of the seasonal variability of ground water levels and quality, surface stream flows and quality, and ambient air quality. This type of preoperational monitoring can be highly useful in that it can document both natural contamination and contamination resulting from past, historical mining activities.

It is important that preoperational monitoring truly reflect conditions which exist. This requires that the monitoring wells (for ground water) or surface stations be adequately located to provide coverage for the facility. In the case of ground water sampling it is vitally important that the monitoring wells be adequately purged to eliminate water which is standing within the bore hole. As is described by Wilson and Rouse (Winter 1983) there frequently are order of magnitude variations between the water standing in a bore hole and the true formation fluids. Pumping of the sample until stable values of pH and conductivity are achieved can do much to assure that the sample is truly representative.

Preoperational sampling should be done under chain of custody procedures such to allow the reconstruction of the "paper trail" of the sample from the time of sample collection until delivery to a qualified laboratory. Chain of custody merely means that

the sampler can document, by written records, the movement of the sample from one person to the other. The sample is considered to be within a person's custody when he has it either in sight or in a locked or sealed container. (Moran & Rouse, June 1981)

During preoperational monitoring, the list of parameters of analysis will generally be more extensive than during subsequent monitoring since it is important to address the potential presences of a number of parameters. As a minimum, Envirologic Services International would recommend the analysis of all major ions (calcium, magnesium, sodium, potassium, carbonate, bicarbonate, chloride, and sulfate together with total dissolved solids), to allow an analysis of the water mass by means of geochemical techniques. In addition, the samples should be collected and analyzed for relevant primary and secondary drinking water parameters such as arsenic, cadmium, chromium, lead, mercury, selenium, silver, iron, manganese, zinc, and copper. If radioactive minerals are associated with the project, radium 226 and 228 concentrations should also be determined.

Operational monitoring, conducted during the life of the project, will require a number of monitoring sites and parameters specified by the operational license. Many times, the regulatory agency can be persuaded to reduce the suite of parameters relative to preoperational monitoring, based on a geochemical analysis of the potential migration of contaminants and their demonstrated absence during preoperational monitoring. The approach would be to monitor for initial, conservative parameters

until they arrive at the monitoring site, and only then to inaugurate subsequent monitoring for less conservative parameters.

Post closure monitoring also will frequently be required by the regulatory bodies, which will specify the parameters of analysis. Post closure monitoring frequently can involve even fewer parameters.

Media Monitoring

The type of monitoring involved with various media will obviously vary greatly. For example, air monitoring can be of two types, stack sampling and ambient air monitoring. The former is conducted by means of carefully specified techniques which traverse facility smokestacks, and are required on a periodic basis by the regulatory agency. Such stack sampling can be highly useful in explaining losses of desired product and in adjusting the operation to achieve better recovery. Ambient air monitoring is specified by the regulatory agency, and probably does fall under the "necessary evil" category.

Liquid effluent sampling is required where there are direct discharges, under a NPDES permit, to receiving surface waters. As in the case of air stack sampling, effluent samples can be highly useful on an operation basis, to control dissolved or suspended losses of desired product.

In the case of liquid effluent sampling, the regulatory agencies frequently require the installation of flow-measurement devices such as Parshall flumes, or V notch weirs. Such flow measurement can be useful in an operational mode, to reduce excess water usage, together with allowing the collection of flow-weighted composite samples rather than time-weighted monitoring. Flow-weighted composite samples are those in which a volume of the sample is collected at a regular time period, with the volume depending on the flow at that time, while time-weighted samples utilize equal volumes of sample collected over each of a number of composite periods. A flow- weighted sample is generally more representative, especially under those conditions where effluent flow varies widely during the process stage. The collection of flow weighted effluent composite samples requires the presence of a calibrated flow measurement device, and the permission of the regulatory agency. (Moran & Rouse, June 1981)

The operational permit will likely specify whether effluent samples are to be reported on a "total" or "dissolved" basis. In the case of total samples, the sample should include suspended material contained in the flow, while "dissolved" samples should be field filtered through 0.45 micron filters prior to the addition of the preservative. Dissolved data are generally more informative, from an operational control standpoint.

Receiving water samples for surface streams are generally collected upstream and downstream of the point of discharge, to allow an evaluation of the impact the discharge has on the

receiving stream. Generally, such receiving water samples are collected on a "grab" basis at a selected location. Care should be taken to assure that the sampling site has adequate mixing across the surface stream. This can be ascertained in the field by a traverse of pH and conductivity readings across the width of the stream. If the stream is deep, consideration should also be given to vertical traversing, to assure that there is not vertical stratification of water quality. (Moran & Rouse, June 1981)

Probably the greatest waste of money in the environmental monitoring area occurs in the collection of inappropriate ground-water samples. Not only can such samples represent a waste of money in that they do not properly reflect true conditions, but the samples can lead to a false sense of security when there actually is a problem or conversely they can cause concern when there is actually no problem. Probably the greatest source of error in ground water sampling results from failure to adequately purge the well prior to sample collection. It has been the ESI experience (Wilson & Rouse, Winter 1983), supplemented by published literature, that there frequently is an order of magnitude variation in water quality between the water standing in a well bore and the true formation fluid. This can be overcome by a knowledge of the hydrologic regime and a careful withdrawal of water, with continuous or intermittent measurement of pH and conductivity until stable values are achieved in the pump discharge. The samples should then be collected, appropriately field filtered through a 0.45 micron filter to

remove suspended material and adequately preserved in accordance with standard procedures prior to shipment to the analytical laboratory. It is important the dissolved constituents in the sample remain dissolved, and not precipitate on the bottom bottle. Therefore, appropriate preservatives should be added to the bottle prior to placing the sample in the sample container.

Experience has shown that many times the results from analytical laboratories bear little or no relationship to the water within the sample. For this reason, ESI routinely collects 15% interlaboratory quality control samples, in which duplicate samples are sent to separate laboratories comparative assay. A blind duplicate intralaboratory quality control sample, intentionally mismarked with a ficticious name, should also be collected at the QC site and submitted to the primary analytical laboratory, along with the original, properly marked sample. A comparison of the three results from the same source is often highly informative and educational.

SUMMARY

Environmental monitoring can be useful as protection against blame for pre-existing contamination, assuming the samples are properly collected, documented, and analyzed. Such sampling can also provide operational personnel information on losses of product material via stack emissions, effluent discharge, or seepage losses from storage tanks or ponds. Environmental monitoring is dictated by environmental regulations, at a

significant cost, but should become an important part of the operational control of a facility.

Heap leaching operations represent a low capital cost approach for recovery of precious metals from tailings, waste rock, or ore, assuming that the loaded leach solution is properly recovered, and not lost by seepage from leach pads or pregnant solution ponds. Many such facilities are located in areas where the water table is far below the land surface. Conventional monitoring wells can be very expensive and do not adequately address such losses. A better approach is to monitor changes in moisture quality within the vadose (unsaturated) zone by means of pressure/vacuum lysimeters. Such units actually draw water from the soil below leach pads or pregnant storage ponds. They are inexpensive to purchase and install and have been accepted for monitoring, in lieu of monitor wells, by various agencies. Their installation is very critical and should be carefully supervised by experienced personnel with prior history of lysimeter installation.

regulations adopt a site-specific approach to mining waste disposal as hoped for by the mining industry.

There are three aspects to determining whether contaminants are leaking to the environment. Firstly, monitoring obtains samples that are analyzed to measure whether ground water quality is being impacted and if so, by how much. Several ways of doing this are reviewed below. In each case, a monitoring grid is required because contamination moves through an underground aquifer in plumes and, unless the sampling pattern intercepts such a plume, a leak can go undetected for years. Monitoring can only detect a leak after a considerable volume of contaminated water has left the impoundment and has migrated at least as far as the monitoring well.

A second approach is to detect leaks early in the impoundment itself. This technique shows where the leak is located, and this can be helpful in planning a repair program. If a leak can be detected early enough, hopefully before contaminants reach the monitor well sampling points, then it may be possible to correct the problem before real damage is done. LANGE (1984) described a geophysical method of leak detection which appears to be useful. His paper is inserted in Chapter 59 on water impoundments and evaporation ponds, and he has subsequently developed another method to conveniently survey beneath impoundments for leaks which looks as though it will prove to be both simple and useful.

UNSATURATED OR VADOSE ZONE SAMPLING

A third and new approach is described by BOND and ROUSE (1985), inserted at the end of this chapter, and mentioned by MORRISON (1984) which involves the installation of Lysimeters which allow very much quicker monitoring of heap leaching and tailings sites as well as storage reservoirs and evaporation ponds. As BOND and ROUSE point out, the conventional perimeter monitor well may take months or years to detect a leak that will be detected within several days or weeks using a properly placed and installed lysimeter.

For the time being, unsaturated or vadose zone monitoring with lysimeters is regarded as an extra safeguard rather than as a replacement of perimeter monitor wells.

GROUND WATER MONITORING - SOURCES OF INFORMATION

Numerous publications review the goals and techniques for ground water monitoring. One useful source is: "Ground Water Monitoring Technology" by Robert D. Morrison and available at $31.00 plus $2.00 shipping ($12.00 outside U.S.A.).

TIMCO MANUFACTURING, INC.

BARCELONA, et al. (1984) evaluated a whole range of groundwater sampling mechanisms. These authors undertook this survey on behalf of the Illinois State Water Survey which is recognized as a leading authority on groundwater monitoring:

ILLINOIS STATE WATER SURVEY
Dept. of Energy and Natural Resources
Champaign, IL
Michael J. Barcelona
Robin A. Miller

Their paper is inserted below as it is an excellent review.

GROUND WATER SAMPLING - SATURATED ZONE

There are several important aspects to ground water monitoring, the ones that come to mind immediately being:

- Validity of the sample.
- The positioning of the Monitoring Well
- The depth in the well from which the sample is taken.
- The equipment used.

Validity of the sample is all important. Is the sample collected representative of water in the aquifer? Is there any possibility of contamination or dilution of the water in the well? Has standing well water been adequately flushed out for a representative sample to be taken? Understanding this latter question is made possible by WILSON and ROUSE (1983) whose paper is inserted below.

The positioning of the monitor wells is also vital. Contamination migrates in plumes, and monitor well positioning should be compatable with what can be learned about the hydrology of the site. BOND and ROUSE (1985) above mentioned the case where a "contaminant leak was detected on a stream bank before it was detected in monitor wells. There is little point in monitoring samples from groundwater at locations that will be missed by contaminant plumes. These days, where CERCLA or Superfund laws are being

enacted, monitoring programs serve to protect the operator--the sooner he finds out about a leak or contaminant excursion, the less costly it is likely to be to repair the "damage." Monitor well positioning to provide a timely warning which would allow corrective measures to be taken before damage has been done rather than after it is too late to avoid damage would, of course, be most useful.

Many monitoring systems are able to seal off the well at a selected level to make sure that ground water is being sampled at a prescribed depth. It is vital that the correct depth is used. Is the sample being drawn from the aquifer of interest or from the one below it?

There are several types of monitoring equipment, most of which are listed and discussed comparatively by BARCELONA, et al. (1984) whose paper is inserted below. They evaluated performance of various available ground water sampling mechanisms for purgeable and gas-sensitive parameters and found that positive displacement bladder pumps were the best of all kinds that they evaluated from that standpoint.

There are several approaches to the equipment used for ground water monitoring:

- Grab Sampling
- Down-the-Hole Pumps
- Dedicated Monitor Pumps
- Down-the-Hole Analysis

Grab Samples

Grab samples drawn with the use of a bailer are the simplest devices as far as equipment and cost of hardware are concerned. These may be useful for very shallow monitoring wells containing a very limited volume of water. This system becomes extremely time consuming and presents samples of questionable validity, especially from deeper wells. Total flushing out of standing well water using a bailer is often impractical. The bailer moving up and down in the casing will cause a fair degree of mixing. Because the bailer must move to the actual point at which the sample is to be drawn, it is not possible to plug off higher levels of the casing to gain control of where the sample is actually being drawn from. Because the same bailer is used from one monitor hole to another, there is a possibility of cross-contamination even if the bailer is rinsed between holes. For a large wellfield, the bailer approach is labor intensive.

A company that specializes in this type of monitor well which involves well casing with a screened end and an innovative bailer is:

GROUND WATER SAMPLING, INC.
West Union Business Park
1855 West Union, #35
Englewood, CO 80110
(303) 781-5589
Geoff Hunken

The entire down-hole assembly of GWSI systems is made of Bisphenol-A Epoxy with fiberglass reinforcement which provides very high strengths and has tested well to show zero priority pollutant leaching. The casing is suitable for all weather installations, unlike PVC which gets brittle in freezing weather.

GWSI claims cost savings resulting from the elimination of on-site casing preparation time and the rapid, simple installation procedures of GWS, Inc. casings compared with other casings available. Rig time for the entire casing installation in a 100-foot well of any diameter is claimed to be six minutes. This vendor claims that for a typical conventional 100-foot well with sand control screens, assembly of the casing, screens, crossovers, and bottom caps, steam cleaning inside and out, and installation down the hole, usually 3.5-4 hours of rig time is required. At 1983 costs, GWS, Inc. claims that their casing can save $500 per hole. The GWS, Inc. casing requires no couplings, adapters, crossovers, or bottom caps, and no field welding or adhesives.

Ground Water Sampling, Inc. offered 4.3" ID wells to 100' at $17.95/foot in 1983, and $11.50/foot for 2.2" ID casing installed to 38 feet.

A second wellknown supplier of bailer sampling equipment is:

TIMCO MANUFACTURING, INC.
Post Office Box 8
Prairie du Sac, WI 53578
(608) 643-8534

Envirologic Services International uses a bailer for some shallow well monitoring jobs in preference to lowering a submersible pump down the hole. The reason is that the bailer is easy and quick to clean between wells, and it is simple to cut off and discard the rope that was submerged in the previous well before lowering the bailer into the next hole. More time is needed to clean out submersible pumps, and the sampling tube as well as the cable, etc. when using the latter.

Down the Hole Submersible Pumps

If a wellfield is to be infrequently sampled--perhaps just once, for example, it would not be practical or economical to install dedicated pumps in each hole. In such cases, as well as in some others where monitoring is more frequent, down-the-hole submersible pumps are often used. There are several to choose from.

Down hole submersible centrifugal pumps such as are used in conventional water wells are used with success. These normally fit down 4"Ø casing which is larger and more expensive to install that some of the other alternatives. These pumps require a power supply--portable gasoline driven generators are used. Depending on the pump size, 4 to 5 kW generators are typically used. One disadvantage of down hole submersible pumps is that they must be raised and lowered which requires time and, in addition, equipment on which to wind the cable and sampling tube.

Down hole submersible pumps can pump at a high flow rate, e.g., 10 to 30 gpm, and are useful also in well drawdown tests. This type of pump is routinely used to depths of 300 feet and fits into schedule 40 PVC casing. By measuring pH, temperature, and conductance of the water while it is being pumped out of the hole, it is possible to tell when the water being samples is representative of the aquifer. Jack Lundberg of Envirologic Services International normally pumps 3 to 4 casing volumes from a well before the sample is taken.

ENVIROLOGIC SERVICES INTERNATIONAL
2425 Suth Colorado Blvd.
Denver, CO 80222
(303) 759-2611
Jim V. Rouse
Jack Lundberg

If the well is not a good producer, the well is pumped dry and allowed to stand. Sometimes it takes a day or longer to fill the well enough to draw a sample in which case, it is not possible to remove 3 casing volumes before taking the sample, and a sample is taken once the well has filled after having been emptied once.

Between wells the pump, cable, and tube must be thoroughly rinsed using tap or deionized water to avoid cross-contamination. If monitoring history shows that the analyses of all wells is very similar, then this is not so critical and by flushing out the standing water in the well, cross-contamination problems will be negligible. If, however, very low contaminant levels, e.g., in the sub-ppm level, are of concern and if the levels vary greatly from one hole to another, then the probability of cross-contamination is high, and great care must be taken. At very low levels of contaminant interest, it may not be feasible to avoid cross-contamination when using down-the-hole submersible systems without excessive care in washing all parts that will come into contact with the water and large volumes of flushing before the sample is taken.

Between jobs, the plastic tubing that comes in contact with the well water is replaced. If, in the course of a monitoring survey there is a chance of contamination because of highly variable levels from one hole to another or if sediment collects in the tube which is not easily washed out, then the tube may be replaced between holes as well.

Envirologic Services International employs four monitoring pumps:

1) Trailer-mounted 4"Ø submersible centrifugal pump capable of pumping from 300 feet and fitting into a schedule 40 PVC casing. This unit requires a 7-8 kW power source. This pump can deliver 30 gpm.

2) A 4"Ø submersible centrifugal pump capable of reaching 150 feet and delivering 10 gpm. It requires 4-5 kW.

3) A 1 3/4"Ø Johnson-Keck pump which fits down a 2"Ø well. This stainless steel constructed pump uses a screw mechanism and can deliver 1 gpm from 100 feet through a 1/2 inch discharge line.

The Johnson-Keck pump illustrated in the Johnson-UOP catalogue below is available from:

4) A teflon bailer is used preferentially for sampling shallow aquifers for organics which are of less interest in the mining industry than in other industries.

Some monitoring companies employ an airlift powered by compressed air to draw samples from monitor wells. Where air comes in direct contact with the sample, these are considered unsuitable if contact with air can result in a change in composition of a sample--e.g., if air oxidizes ferric to ferrous ions, or introduces CO_2 which may precipitate carbonates from the water before it is sampled.

Peristaltic Pumps

Another innovative method for down-the-hole monitoring for very shallow lifts down to 26 feet are the light-weight, portable, battery operated peristaltic pumps which are very inexpensive and which can pump 2-3 liters per minute. Two suppliers of units were identified:

Down-the-Hole Analyzers

For macro water quality surveys, yet another approach is possible. Down-the-hole analysis avoids the need for sampling although once again, the question of whether standing water in wells is representative. An example of this type of equipment is the Digital Water Quality Analyzer produced by Martek.

DEDICATED MONITOR PUMPS

Dedicated monitor pumps can avoid many problems and, at the same time, save many dollars in labor costs. Dedicated monitor well pumps would be of particular interest where:

- Wells are relatively deep, say 100-150 feet.
- Low levels of conamination are of concern, so cross-contamination is a bigger problem.
- Multiple repetitive sampling programs are anticipated.

Dedicated monitor well pumps and tubing save the time not only of hauling and lowering the pumps, but also the time it would otherwise take to clean them between sampling.

When lowering a pump down a hole, there is always a risk of it sinking into the sediment at the bottom if it is lowered just a little to far--then the pump and tube and any filters get loaded with sediment that must be cleaned out and which can alter the water sample composition.

Very often, a sample is needed of a particular level only. Dedicated monitor wells are suspended at a very specific depth, and this does not constantly have to be changed going from one well to another. Also, by using an air bladder to isolate one section of the well, the amount of standing water that must be flushed from a well before a valid sample is taken can be greatly reduced.

Dedicated monitor well pumps avoid any questions of cross-contamination. They are available in inert material such as teflon and PVC that will not contaminate water either.

Because the tubing and pump remain in place dedicated to each well, the equipment required to sample wells using pumps is minimal. Usually, a battery-powered compressor and a controller are all that is required. These are highly portable and suitable for getting to wellsites that would be hard to reach by pickup truck.

Several dedicated monitor systems are available on the market. Of these, the best appears to be one offered by:

QED ENVIRONMENTAL SYSTEMS, INC.
Post Office Box 7209
Ann Arbor, MI 48107
(313) 995-2547
Fred Bernardin
President
Dave Kaminsky

The QED system is described in the following brochures. These are light weight and made of inert materials with no moving parts down in the down-the-hole system. Solution pumped from the wells does not come into contact with air.

Dedicated monitor wells are used increasingly in municipal landfill monitoring programs and around hazardous waste sites. They have only recently been introduced to the mining and milling industry, and it is expected that these will in due course become the most commonly used technique, primarly because of the man hours that they save and because they avoid any possibility of cross-contamination. As water quality standards increasingly specify parts per billion levels and the possibility of cross-contamination becomes increasingly important, so dedicated monitor wells will become more popular. It is very easy to contaminate a sample with a fraction of a ppm of a contaminant, and the consequence of high readings in monitored sample assays is so serious that this risk is not worth taking. A final advantage of these light weight sampling devices is that they are simple to use and virtually anyone can be shown how to operate them without the risk of things going wrong.

Attention is drawn to the photograph shown below of an automatic sampling device installed at the effluent discharge point of a mine-mill complex in New York state. This type of device works very well. However, possibly not very clear in the reproduction of the photograph is the algal matte suspended in the water. Algae frequently thrive in flotation mill effluents (apparently their growth is encouraged by species such as some flotation reagent degradation products, but this is not clearly understood). Algae take up metals from solution and if loose fragments of these algae were to get into the sample, this could give a bias to the analysis which could indicate a higher metal content than is really there. When drawing samples by hand, and particularly when relying on unattended automated effluent samples, this factor should be borne in mind.

Lysimeters allow quicker monitoring of heap leaching and tailing sites

William R. Bond and Jim V. Rouse

Pressure/vacuum lysimeter use at mine sites has proven to be a valuable early warning system for detecting leakage of precious leachate fluids. Such a device can detect solution leaks in several days or weeks, whereas a conventional perimeter monitor well may take months or years.

Introduction

The pressure/vacuum (p/v) lysimeter or soil water sampler has become useful for monitoring vadose zone or unsaturated zone water conditions. The soil water sampler was first introduced around 1961. It was used as a monitoring and research device for studies in agriculture and soil contamination around landfills. Since then, it has been used for many purposes.

The use of p/v lysimeters at mining facilities to monitor for solution loss is a relatively new idea. The primary purpose of the lysimeter here is to function as an early warning system. It detects leakage through liners of tailings ponds, heap leach pads, and leachate holding ponds. Their use has proven valuable for collecting baseline data and detecting loss of precious leachate fluid.

Different lysimeter designs are capable of vadose moisture sampling from near the surface and down to 90 m (300 ft). They are also capable of sampling soil moisture or saturation plume contaminants from areas not accessible by conventional water well installations.

William R. Bond and **Jim V. Rouse**, member SME, are staff supervisor and principal, respectively, for Envirologic Services International, 2425 S. Colorado Blvd., Denver, CO 80222.

The most common installations are usually simple and cost-effective. In many cases, they can be installed without the use of heavy drilling equipment. A properly placed and installed lysimeter can detect solution leaks in several days or weeks. A conventional perimeter monitor well may take months or years to detect a leak of the same magnitude.

A discussion on the general design and installation of p/v lysimeters will give an understanding of its versatility. Three case studies of lysimeter installations at mining sites will be examined in detail.

Design, Installation, and Sampling

Design

The basic design of a p/v lysimeter chamber consists of a porous material through which the soil is drawn into a collection chamber. Access tubes run from the unit to the sample station at the ground surface. Most units currently available range from 25 to 76 mm-diam (1 to 3 in.-diam).

The sample collection chamber, or body, can vary from 0.6 to 1.8 m (2 to 6 ft) in length. The body can be constructed of PVC casing or Teflon, depending on the installation desired. The collection chamber functions as a holding reservoir for the collected soil moisture.

The intake, or porous material, on the lysimeter is the most complex and vulnerable portion of the unit. The pore size selection varies based on the needs of the installation, type of fluid to be sampled, and type of soil material surrounding the unit. Teflon (PTFE) and porous ceramic are used in fabrication of the porous inlet portion.

When using a Teflon material, which is hydrophobic, a larger pore size of 70 μm is needed to overcome surface tension and draw water into the collection chamber. It is typically used at sites involving organic contamination, because of its inert properties.

Ceramic material is generally hydrophilic, having less surface tension. Therefore, it has a smaller porosity range to conduct the moisture through the porous medium while under vacuum. Pore sizes may be selected from 0.16 to 6 μm, and can be manufactured for the specific needs of the installation.

The final major design component of the p/v lysimeter is the access or sampling tubes. The tubes are usually of 6.3-mm-outside-diam. (0.25-in.-outside-diam). They are made of rigid polyethylene or flexible Tygon with a wall thickness of 1.5 mm (0.06 in.). The con-

nection of the access tubes depends on the type of lysimeter being installed.

On the shallow lysimeter model, for use at less than 15 m (50 ft) of depth, the tubes are inserted through two holes in the neoprene rubber top of the shallow unit. They are individually designated as a p/v line or discharge line.

Deep installations involve high p/v lysimeters that use internal check valves. These lysimeters are equipped with brass tube fittings connected to the access portals on the top of the unit. The attachment procedure of the access tubes also depends on the manufacturer and specific design of the unit. In most cases, the outer surface of the tube connection is sealed with a silicon caulking.

Beyond the basic design of the p/v lysimeter, variations have been made in the intake medium position on the chamber, the access tube installations, the construction material used, and the use of vacuum gauges for readout of internal residual vacuums. But the standard design and function of the unit, drawing capillary or available moisture from the vadose zone and sample retrieval, remains the same.

Installation

Installation techniques for permanent placement of p/v lysimeters are varied. The high pressure unit can be installed at depths up to 91 m (300 ft) below grade or serviced by sample tubes up to 152 m (500 ft) in linear distance.

Several different installation procedures allow for placement of the units in subgrade soils before building a permanent leach pad, pond facility, or tailing disposal structure. The access or sample tubes are then buried in trenches. Their sample stations are located at a considerable distance from potential disturbances due to traffic and future construction. Before choosing the type of lysimeter and bedding medium for the final placement, several questions should be answered and several conditions must be satisfied.

First, what kind of mining facility is being considered, and are lysimeters the right tool for monitoring? Lysimeter monitoring has been found to be effective at heap leach facilities when placed under the heap leach pad areas and below the pregnant, barren, and overflow ponds. They are also being used successfully as leakage monitoring devices around old and new tailings pond disposal areas.

In the case of old, leaking tailings pond disposal areas, they are useful in detecting the concentration of contaminants and direction and size of existing leakage plumes. In newly constructed mining facilities, they are being readily accepted by regulatory agencies as a first-line warning system to detect leakage through synthetic liners.

Lysimeters are not designed to function as remedial action tools and should not be considered as such. They are designed to detect leakage problems early enough to allow adequate planning before the leak becomes a vadose and ground water pollution problem.

What is the geology of the area where the mining facility will be constructed and in which horizons will lysimeters be used? Lysimeters may not be an appropriate monitoring tool in areas of shallow water tables or dense rock formations. In shallow water areas, they will easily obtain samples. But monitor wells may be more efficient.

Lysimeters are not well adapted for sampling vadose moisture from dense, unsaturated, hard rock materials. They are more appropriately used in areas of unconsolidated materials. These include weathered bedrock, glacial till, unsorted alluvial material, and deep soil horizons. In general, the less consolidated and finer materials — such as silts, clays, fine sands, and mixtures thereof — yield vadose water more readily than fractured crystalline rock, cemented sandstone, or very coarse sand.

The chemical nature of the leachate fluid that may leak into the vadose zone should be considered. Highly acidic fluids or highly alkaline fluids may not be readily sampled by all lysimeter installations. Consult the lysimeter manufacturer before selecting the units.

It also should be determined which chemical components of the leachate solution will be most mobile in the geochemical regime of the local vadose zone. These el-

TYPICAL LYSIMETER INSTALLATION AT A HEAP LEACH MINING OPERATION

ements or compounds are then used as indicator parameters to determine possible leachate solution losses or migrations.

Site access is an important consideration for installation of lysimeters. Preferably, they should be installed before or during construction of the facility. With difficulty and less efficiency, they can be installed after construction is completed. In the case of heap leach pads and solution ponds, it is imperative that the units be installed before completing the subgrade and liner emplacement.

When installing lysimeters around ponds, angle drill holes can be used to place units around the pond bottom perimeter. It is also imperative that the sample tubes be safely buried. And they must terminate in a location that is out of danger for long-term sample station establishment.

The earthmoving contractor should know the installation procedures and equipment needed when building a lysimeter installation. Trenching machines, road graders, bulldozers, and other machines have been known to damage and cut lysimeter sample lines after they have already been buried.

The length of the sample lines under pads and ponds, and their relative gradient from the lysimeter should be considered for final location of sample stations. In several instances, up to 152 m (500 ft) of sample line has been used in conjunction with high p/v lysimeters.

It is important to consider the head differential from the lysimeter unit to the sample station and the friction involved with forcing the water sample through a small tube over a long distance. Lysimeter units without check valves may be appropriate for installations of up to 15 m (50 ft) of head differential. But they may not be suited for several hundred meters of sample delivery line that may be necessary for their final installation.

In general, if an installation involves more than 15 m (50 ft) of head differential or more than 30 m (100 ft) of sample line distance, high p/v lysimeters with check valves to control sample retrieval pressures should be used.

The most desirable emplacement of the porous ceramic cup lysimeter is usually in an in situ setting. The small pore size and hard surface area of the porous ceramic enables a direct contact between soil particles and the cup with little effect of soil clogging the ceramic. This type of installation has been quite successful in finer grained materials.

The in situ setting of the lysimeter can be accomplished using a drive tube or split spoon soil sampler of the same diameter as the lysimeter. When the drill hole depth is just above the desired sample horizon, the soil sampler is driven to form the final setting in the material to be monitored.

The lysimeter is then fed down the drill hole by a placement pipe. It is pushed into the drive tube sampler hole fitting firmly into the soil. The placement pipe can then be removed by sections or it can be left in place as protection for the sampling lines. The unit can then be backfilled with ben-

DIAGRAM OF PRESSURE-VACUUM LYSIMETER INSTALLATION

3675

tonite material or screened drill cuttings as the installation dictates.

In coarse sand, alluvium, and loose fill material, a bedding material, such as crystalline or flour silica is needed. The silica flour bedding material acts as an artificial soil to surround the porous intake medium of the lysimeter when the natural soil conditions or contaminant type does not allow for an in situ setting. This type of backfill bedding is used exclusively when installing Teflon type lysimeters.

When the drill hole has reached the desired depth, the lysimeter is inserted down the hole. The hole is then backfilled with crystalline silica flour that has been mixed in a distilled water slurry. After placement of the silica bedding, the hole can be completed with a bentonite seal and backfilled.

One drawback of this method is that the first several samples obtained from the lysimeter will be diluted with distilled water. But, after an average of three sample collections, distilled water should no longer be a factor.

Drilling equipment needed for lysimeter installation includes hollow stem auger drill rigs (preferably) or hand-dug post hole augers for shallow settings. It is recommended that in firm material or depths greater than 3 m (10 ft), an auger drill be used. The hollow stem of the 152-or 203-mm (6-or 8-in.) auger is ideal for access to the bottom of the drill hole for emplacement of the lysimeters. Trimmy lines can be used to emplace the silica flour slurry and bentonite seal at the desired depths. Other drilling methods have the potential for collapse of loose material in the drill hole. This greatly jeopardizes proper installation of the unit.

A final item to consider for the installation is a permanent sampling station. Typically, this involves using a length of PVC or steel pipe buried vertically, 1 m (3.3 ft) into the ground as a surface casing.

The sample lines should be set through the surface casing before setting and should extend 0.9 to 1.5 m (3 to 5 ft) from the top of the casing. This allows for easy sampling of the unit while placing sample equipment on the ground. After sampling, the access tubes can be coiled up and placed inside the protective casing. In areas subject to possible tampering or vandalism, a more secure steel surface casing with a locking cap should be used.

Sampling

Several different sample collection procedures have been developed to contain the often limited amount of soil water. After the unit has been installed and the sample tubes buried in trenches to the designated sample station, a vacuum is drawn on the unit. A handheld vacuum pump is attached to the designated p/v line. A vacuum is then drawn on the unit that is compatible to the type of soil material where it has been installed. Vacuums will range between 254 to 457 mm (10 to 18 in.) of mercury vacuum. In general, higher vacuums are applied to tighter, finer materials, and lower vacuums to more coarse, sandy materials.

After the desired vacuum has been applied, the clamps on the neoprene tubing are closed tightly to secure the vacuum. Several days or even a few weeks must pass before attempting to retrieve a water sample from the lysimeter. During this time, the handheld vacuum can easily be attached to the p/v line. The clamp can then be released to allow reading of the residual vacuum in the unit. In many cases, it is desirable to have a permanent vacuum gauge attached in-line for constant readout on lysimeter vacuum. When the residual vacuum has dropped substantially within the unit, or sufficient time has passed to allow collection of soil water, a sample may then be retrieved. Before a sample collection is attempted, the residual vacuum on the lysimeter should be recorded. An ongoing record such as this will provide valuable information to indicate the time needed to absorb a sample, the volume expected to be recovered, and the drop in vacuum attributed to the sample volume recovered.

The vacuum is then released from the lysimeter. An air pressure source is attached to the same p/v line. The air pressure source may be a hand-operated pump or a compressed air tank.

In cases where atmospheric oxygen may alter the water sample parameters being analyzed, a nitrogen gas tank source should be used. In this way, atmospheric oxygen contact with the sample is limited. And the lysimeter unit itself is purged with the nitrogen gas, leaving an inert atmosphere within it.

The discharge line should be cleaned and placed in an appropriate sample collection container. A clean sample container should be obtained from the laboratory that will perform the analyses. It should also be properly preserved before emplacement of the collected water sample.

Usually, a glass or polyethylene lab bottle is supplied for collection of samples. The bottle should have volume gradation markings to allow the sampler to record the volume of soil water. In those cases involving sampling that must eliminate contact with atmospheric oxygen, a method has been developed using a 50-cm³ (1.7-oz) syringe to collect the sample for shipment to the lab.

This method involved inserting the tip of the syringe, without the needle, into the discharge opening. Pressure is fed into the lysimeter and a water sample is forced out. The syringe plunger is withdrawn and the container fills with the sample, thus avoiding direct contact with atmospheric oxygen.

Patience must be used when applying pressure to the lysimeter sample line. In many cases, sample lines are long enough that the

Where atmospheric oxygen may alter the water sample parameters being analyzed, a nitrogen gas tank should be used as a pressure source. In this way, atmospheric oxygen contact with the sample is limited and the lysimeter unit is purged with the nitrogen gas.

travel time for the sample may be several minutes. It must be remembered that in the regular p/v lysimeters, check valves are not used to eliminate the possibility of forcing the sample back through the porous material. Usually, if the unit has collected a sample, it will discharge within a minute. If the unit is dry or only a small sample has been collected, a gurgling noise or escaping air can be heard coming from the discharge line. After the sample has been recovered, the discharge line clamp should be secured and the desired vacuum reapplied to the unit.

Examples of P/V Lysimeter Installations

Uranium Tailings Pond

This installation involved placing 15 high p/v lysimeters around the base perimeter of a newly constructed, membrane-lined, uranium tailings disposal pond. It is located in glacial outwash deposits in Washington. The pond received tailings from an acid leach circuit. Before building the pond, the old tailings were discharged to adjacent, unlined ponds.

The need for an early warning leak detection system became apparent when a seepage plume from the old ponds was detected in a streambank seep and nearby monitor well. The site topography and stratigraphy allowed the seepage plume to discharge on a nearby streambank before its detection in the monitor well.

As a follow-up to the plume investigation, it was suggested that p/v lysimeters be used as a leak detection device around the new pond. The mining company personnel agreed with concept. The idea was forwarded to the Nuclear Regulatory Commission (NRC).

After lengthy negotiations between Envirologic Services (ESI) and NRC, a location plan was developed for the installation of the 15 p/v lysimeters. At the time of installation, May 1981, the use of the p/v lysimeter as a tailings pond leak detection device was, to the authors' knowledge, the first of its kind.

In defining the depths and locations of the lysimeters, consideration was given to the nature of the glacial till material and the potential configuration of a leakage plume. Prior investigation by ESI on the earlier leakage from the old pond was done by resistivity and monitor wells. This gave a good indication of the dimension and character of movement of a possible contaminant plume.

The final specifications for emplacement of the lysimeters involved auger drill holes about 11 m (35 ft) deep from a midpoint construction bench on the side slope of the pond. The holes are located about 61 m (200 ft) apart. They terminate at about the same 11-m (35-ft) depth, except where shallow bedrock prevented further drilling. The pond volume is about 1.5 hm^3 (1200 acre-ft). Its average depth is 21 m (70 ft). The construction bench is about 9 m (30 ft) above the base level of the pond. Therefore, most lysimeters are located about 1.5 m (5 ft) below the pond bottom.

The emplacement of the lysimeters involved the previously discussed in situ setting technique where the porous ceramic cup tip is fitted into a 50-mm (2-in.) drive tube hole for tight soil contact. The hole was then backfilled with a bentonite plug and screened glacial till. The upper backfill surface material was tamped with a shovel handle. This avoids additional settling and conduit of precipitation during completion of construction.

Timing of the lysimeter installations into the contractor's overall schedule was very important. The most critical aspect was the completion of all rough grade work for the pond base. The drill rig was then mobilized and installation began without concern for disturbing the finished grade.

Before installing the lysimeters, it was emphasized that all rough grade work be completed to avoid disturbing the units and sample lines. After installing the lysimeters and backfilling the boreholes, a small trenching machine was used to dig a trench from the top of the borehole to the rim of the pond. A final sample station for each lysimeter was constructed on the pond rim. Care was taken in backfilling the trenches to avoid crushing the lines.

The sampling of the lysimeters began within one week of their installation. This was an effort to secure baseline vadose moisture samples before completion of the pond liner and disposal of tailings. The average volume recovery from the lysimeters is 0.15 to 0.2 L (0.04 to 0.05 gal) of water.

At the time of sample collection, the samples are checked for field pH and conductivity. An ongoing record is kept of these parameters to note variations from the established baseline data. These two parameters are indicators of the possible migration of acid mill wastes through any leaks in the liner. Collected samples are then appropriately bottled and preserved as necessary for lab assay.

A sufficient volume of water cannot be obtained with any regularity. Therefore, radiochemical analysis is not possible on all samples collected. Existing studies document that radiochemical contaminants are retarded by ion-exchange reactions in soil, in comparison to other more conservative parameters. For this reason, samples are analyzed for other, more mobile parameters such as pH, specific conductance, TDS, sulfate, U_3O_8, NO_3, manganese, chloride, NH_4, COD, and iron. These also require less sample volume for detection.

The parameter list was agreed on through negotiations with NRC. The parameter selections were de-

termined using information from the prior investigation of seepage at the disposal site.

Gold Heap Leach Facility

The gold mine facility studied lies in a hilly, mountainous area of the North Black Hills of South Dakota. The selection of p/v lysimeters was decided in part to satisfy concerns of state regulatory personnel. It was also to assure the mining personnel that precious pregnant solution was not being lost to the subsurface.

Lysimeter units were used under both pad liners and solution holding ponds. The site is underlain primarily by weathered and fractured limestone. The heap leach pad construction removed all overburden organic materials, leaving as much clay veneer as possible over the limestone.

In most instances, the lysimeter installations are at or below the clay-limestone interface. The installation depths varied from 0.6 to 2.4 m (2 to 8 ft). Drilling was easily conducted with a Mobile auger rig using 100-mm (4-in.) auger sections. Shallow installation depths allowed for several holes to be drilled and logged in succession.

The lysimeters were then easily installed without using the drill rig. Specifications for the emplacement of the units involved a dry bedding of silica flour around the porous ceramic tip of the lysimeter. The silica flour bedding was then capped with a bentonite seal 0.5-m (1.5-ft) thick.

The main difficulty with installation was associated with trenching through the weathered limestone material and clays for safe burial of sample lines. The original specifications called for a 0.5-m (1.5-ft) trench with the lines buried in clean bedding sand in the bottom one-third of the trench. The presence of the cobble-sized limestone material made trenching difficult. It also jeopardized the integrity of the sample lines. To remedy this, the sample lines were fed through 25-mm (1-in.) PVC casings and laid in the trench.

The trench was then backfilled with bedding sand to minimize the risk of line damage during subsequent backfilling and compaction. This trench backfill technique was used under the heap leach pad area and under the pregnant, barren, and overflow ponds. In several cases, sample lines were buried that were up to 122 m (400 ft) long from sample station to lysimeter unit. Coordination and timing with the earthmoving contractor was essential.

> There is growing interest in heap leach techniques to recover precious metals from low grade ores. So the monitoring of leach solution flow balance is a primary concern for production efficiency.

Samples were first collected one month after installation to establish baseline information. All lysimeters are now being sampled on a regular basis. Negotiations with state regulatory personnel were required to determine a suitable lysimeter array and priority list of parameter analysis.

Old Tailings Deposits

Pressure/vacuum lysimeters were very useful in determining the migration of arsenic and other contaminants within old tailings deposits on a river floodplain. Lysimeters were used to recover soil water samples from the tailings in the vadose zone. Saturated zone sampling suggested a complete understanding of arsenic migration in the tailings could not be determined solely by ground water and soil sampling. Data collected from lysimeters in this study proved valuable in formulating the movement of arsenic and other contaminants within the tailings.

A total of 24 lysimeters were installed at 11 different sites over a 14.5-km (9-mile) stretch of the study area. At each site, an array of ground water wells and lysimeters were installed. These obtained water samples from the various horizons of native material and tailings.

All sites included one deep monitor well installed in the local bedrock, one or more monitor wells in the stream alluvium and overlying tailings, and lysimeters at various horizons within the unsaturated portion of the tailings. Some areas involved nests of three wells and up to five lysimeters. With this array, it was possible to correlate the analytical data to determine the relative-vertical movement of the elements of concern.

All lysimeters in this study were installed using the in situ method. The drill rig was a CME 55, using 152-mm (6-in.) hollow stem augers. In installations less than 1.8 m (6 ft) deep, hand augering was done. Drive tubes were then used to form the setting hole for the lysimeter tip. All holes were then backfilled with a bentonite seal and screened tailings material.

The tailings material was tamped to prevent excessive downward percolation of rain water. Sample stations were established directly above the lysimeters in this case by using 76-mm (3-in.) PVC casings supported with standard steel fence posts.

All lysimeter units installed in this study were purged with nitrogen gas before applying the first vacuum. Nitrogen gas pressure tanks were used in subsequent sampling.

Sampling of the lysimeters involved both the sample bottle method and syringe container method. The latter method was developed during the study when it became apparent that samples had been altered by atmospheric oxygen during collection and subsequent transport to the lab. After collecting water samples in the syringes, they were quickly frozen in dry ice-alcohol bath and maintained in a frozen state for shipment. This supplied confidence to the values of arsenic and iron speciation that were determined during the analyses.

Final results indicated that, in contrast to previous assumptions on the vadose water movement in the tailings, there was actually a net upward migration of the contaminants due to capillary attraction. ■

Here's a whole bookshelf of state-of-the-art...field proven...equipment advantages and disadvantages...step by step procedures...detailed diagrams...

Ground Water Monitoring Technology; Procedures, Equipment and Applications, by Robert D. Morrison

There is nothing else like it available anywhere. Nothing even remotely similar.

Ground Water Monitoring Technology details *only* the field-proven state-of-the-art procedures, equipment and applications for monitoring in the vadose *and* the saturated zones with...

- 132 7" X 10" pages
- 88 diagrams, illustrations and photographs—"a picture is worth a thousand words"
- 35 equations—leave no doubt about the specific points defined
- 454 references arranged by subject—you can personally investigate the theories that led to the field-proven methods
- detailed glossary—includes all major technical terms used in the book
- metric conversion tables—no need to carry extra reference material in the field
- complete subject index—makes it easy for you to answer all your questions

Ground Water Monitoring Technology is a practical, useable handbook for your office and in the field. It has...

- good looking dark blue leatherlike grained cover with gold imprinted title on the cover and the spine
- tough hard cover bound—so it can "take it" in the field
- smythe sewn with head and tail bands (not glued)—you wont lose any pages
- printed on heavy nonglare 80 pound paper
- space on each page for your notes
- cover overhangs 1/4" on all 3 sides—minimizes scuffed page edges

Ground Water Monitoring Technology contains the following...

- Monitoring in the vadose zone
- Soil moisture potential
  - Laboratory methods
  - Field methods
    - Tensiometers
    - Thermocouple Psychrometers
- Soil moisture content
  - Laboratory methods
  - Field methods
    - Electromagnetic methods
      - Soil moisture blocks
      - Four electrode method
      - Capacitance sensors
    - Electrothermal methods
    - Nuclear methods
      - Neutron thermalization
      - Gamma ray attenuation
      - Nuclear magnetic resonance
- Soil salinity
  - Salinity sensors
  - Four electrode method
  - Electrical conductivity probes
  - Inductive electromagnetic methods
- Temperature
- Soil pore water sampling
  - Vacuum pressure lysimeters
    - Ceramic cup lysimeters
    - Nylon lysimeters
    - Fritted glass lysimeter
    - Teflon® lysimeters

Ground Water Monitoring Technology was written by Robert D. Morrison who is currently a geohydrologist for Woodward-Clyde Consultants, Santa Anna, California. His primary interest and expertise is vadose and saturated zone monitoring. He received his B.S. in geology from the University of Redlands, California; an M.S. in environmental hydrology from California State University, Fullerton, California; and an M.S. in environmental engineering from the University of Southern California (USC). Mr. Morrison is currently completing work for a Ph.D. from U.C.L.A. in applied sciences. Robert Morrison has authored and co-authored many articles which have been published in many of the major industry trade and technical journals.

VARIATIONS IN WATER QUALITY DURING INITIAL PUMPING OF MONITORING WELLS

Because standing well water may differ significantly from formation water, pumping and sample methods must be designed to minimize sample contact with atmospheric gas. The authors illustrate water variations over time.

by Lee C. Wilson and
Jim V. Rouse

The objective of most ground-water monitoring programs is the determination of ambient water quality in a particular aquifer or aquifers. The details, and thus requirements, of each program are site specific; however, the need to obtain the most representative and undisturbed water sample possible is usually of primary importance in any study.

Water lifting, filtration and preservation methods have all shown an effect on measured parameters in water samples. Filtration, preservation and other sample handling factors have been studied in connection with surface, as well as ground-water sampling. However, methods of sample lifting and adequate well purging are unique features associated with ground-water sampling. Our experience, as well as that of others (Schmidt 1977; Schuller et al. 1981; Humenick et al. 1980) indicates that pumping a well is necessary to obtain a representative aquifer sample. Bailers will deliver an unaltered sample of well water to the surface, but water stored in a well bore often has significant chemical differences from the water in the aquifer. If an aquifer sample is desired, water must be drawn from the aquifer rather than merely the column of water standing in a well. Then, the water must be transported to the surface, filtered, preserved and shipped to the analytical laboratory with as little alteration as possible. This article discusses relationships between field parameters and laboratory analyses of water samples collected as well pumping progresses.

Previous Work

As a result of improved analytical sensitivity and monitoring requirements, numerous workers have recognized the need for additional investigations related to the adequacy of ground-water sampling procedures. Pump equipment, bailers, filtration apparatus, preservation technique and effects of pumping time have been studied and compared (Summers and Brandvold 1967, Schmidt 1977, Summers 1972, Kelly 1982, Schmidt 1982).

Schuller, Gibb and Griffin (1981) offer criteria for selection of pumping apparatus, procedures for determining the necessary extent of well flushing and procedures for sample preparation, preservation and storage. They indicate the site-specific nature of sampling protocol, point on the desirability of pumps vs. air or nitrogen lift mechanisms or bailers and indicate a desirable range of well volumes (4 to 6) to be removed prior to sample collection. In addition, they indicate the need for pH, Eh and specific conductance measurements to determine adequacy of well purging. Humenik, Turk and Colchin (1980) discuss sampling near in situ uranium leach operations in which field and laboratory parameters are compared in relation to pumping rate, duration and installation depth. Completion and pump rate were shown to be particularly important; again, field parameters were instrumental in determining adequacy of purging.

Many authors point out the necessity of well purging prior to sample collection, as well as the utility of using field parameters to determine adequacy of purging.

Experimental

The data comparing field parameter trends to dissolved constituent variations were collected in conjunction with water sampling in areas affected by mining and milling activities in the western U.S. The data from wells WC were obtained from flood plain deposits downstream of an historic gold district in which cyanide mill tailings were transported and deposited. Most of the other comparison samples were collected during extended pump tests in an area affected by open pit copper mines, leach facilities and mills. In addition to these specific comparison analyses, similar field data trends have been documented in sampling studies located throughout the western U.S. in areas surrounding uranium, silver, coal, copper and gold mining and milling operations, as well as hazardous waste disposal sites.

This article concentrates on the collection of multiple samples and the simultaneous measurement of field parameters as monitor well pumping progresses. The first sample was usually collected immediately after water began flowing from the pump discharge line. Thereafter, samples were collected at intervals designed to correspond to progressively larger numbers of bore volumes removed from the well. The wells WC sampling was performed using a small, battery-operated pump at the surface. In our experience with western sampling, shallow water levels allowing the use of surface pumps are the exception rather than the rule. Well A-1 was pumped with a permanently installed turbine pump. The other comparison data were gathered in conjunction with extended pump tests using a trailer-mounted submersible pump unit. This unit consists of a self contained generator that powers a 10cm (4-inch) diameter stainless steel submersible pump and a powered reel with 91m (300 feet) of discharge hose. This pumping unit allows sampling of monitor wells without the permanent installation of a pump. Other advantages include immediate and relatively easy adjustment of pumping depth during sample collection and the pumping of samples where no power facilities are easily accessible.

The discharge hose from the sampling trailer has a sample bleed that allows a portion of the discharge to flow through a chamber containing pH, specific conductance and temperature probes. This arrangement assures that there will be a minimum mixing of sample water with atmospheric gases prior to the measurement of field parameters. The flow-through chamber also maintains all probes in a stabilized temperature bath as pumping progresses. In some instances continuously recording pH and specific conductance meters were installed in the flow-through chamber. A continuous record of field parameters can be a significant advantage if extended pumping is expected to produce break-through of contaminants from a nearby source.

All field parameters were taken using techniques specified in a sampling protocol document (Moran and Rouse 1981) which is based on U.S. EPA and USGS procedures. Sample filtration and preservation were also performed on-site as prescribed in this protocol document. Samples were transported to EPA-approved laboratories within holding time limits outlined in the sampling protocol document.

Because many investigators routinely use bailed samples and there are times when sampling is limited to this technique, a comparison was done in which both bailed and pumped samples were collected from a well. The bailed sample was collected shortly after well completion and development by means of air-lifting. The pumped sample was later collected using a submersible pump and monitoring of field parameters until stable conditions were achieved. Multiple samples were not collected during well purging.

Throughout the multiple sampling study, a great amount of care was taken to maintain uniform sampling technique and high sampling accuracy; however, a certain amount of site-specific variability is always present. Knowledge of the hydrologic regime into which the monitor well is installed can be very important for the correct interpretation of field parameters and sample collection timing. The other major site-specific variable that goes hand in hand with an understanding of the subsurface environment is detailed, accurate information concerning well completion. The data presented comparing field parameters to analytical results were obtained from wells in which drilling and completion had been supervised by the authors or where good geologic and completion records were available.

Site-specific geohydrologic or well-completion details were considered in the selection of pump intake depths. The hydrogeology and position of slotted sections in the wells can be very important factors when deciding pump-setting depth and rate of pumping. When pumping from wells with sealed, piezometer-style completions, the pump is normally set just above the screened section. This allows water from the entire (usually short) screened section to flow upward to the pump intake while reducing the need to pump out the entire column of water above the pump. Humenick et al. (1980) studied pump-setting depths and found a deep setting (near the zone to be monitored) and low pump rate to be advantageous.

Well Completions

In the case of the WC sampling, the wells are relatively shallow. The other monitor wells are completed in more complex regimes with two or more aquifers. Wells WC-1, WC-2 and A-1 are designed to monitor the entire saturated section, while wells A-2, A-3, A-4 and A-5 are completed as piezometers to monitor only the lowest aquifer.

Well WC-1 has a total depth of 9m (29 feet) through interlayered alluvial sand, gravel and silt. The sand and silt fractions contain a high percentage of stream-transported gold mill sands and slimes. Casing is 5cm (2-in.-h) diameter PVC with annular gravel pack and saw cut slots in the bottom 3m (10-foot) section. Depth to static water level was 0.8m (3 feet) below land surface and the suction hose was set at approximately 6m (20 feet).

Well WC-2 is completed through similar alluvial material to a total depth of 5.4m (18 feet). It is also cased with 5cm (2-inch) PVC with gravel-packed annulus. Static water level was 2.2m (7.4 feet) with the suction hose set at approximately 5m (16.5 feet).

Well A-1 is 76m (250 feet) total depth with static water level at 15m (50 feet). This well is completed through an alluvial conglomerate containing variable lenses of coarse sandstone and clay-rich sandstone interbedded with sandy and clay-rich conglomerate. Casing is 40cm (16-inch) steel perforated from surface to total depth. A 760 liter/min (200 gpm) turbine pump is installed in A-1.

Well A-2 has a total depth of 47m (154 feet) with static water at 1.4m (34 feet) and is cased with 10cm (4-inch) PVC casing. Well A-2 is completed through mixed gravel, sand and silt alluvium to 30m (98 feet), clay-rich sand from 30 to 31m (98 to 102 feet) and bottoms in sandy, silty conglomerate from 31 to 47m (102 to 157 feet). The casing has commercial saw-cut perforations from 41 to 47m (135.3 to 157 feet) with a bentonite seal at 40m (132 feet). This well was pumped at 18.5 liters/min (4.8 gpm) with the pump set at 40m (132 feet).

Well A-3 is completed to a total depth of 48m (157 feet) through 22m (72 feet) of clayey sand and gravel alluvium, sandy clay from 22 to 24m (72 to 80 feet) and sandstone and sandy conglomerate from 24m (80 feet) to total depth of 48m (157 feet). The well is cased with 10cm (4-inch) PVC casing with commercial saw-cut slots from 42 to 48m (137 to 157 feet) and a bentonite seal at 40m (130 feet). Depth to static water level was 3.7m (12 feet). A-3 was pumped at 26 liters/min (6.8 gpm) from a depth of 38m (125 feet). The last two samples of the sequence on figures A-3.1 through A-3.3 were collected after extended pumping at a rate of 10 liters/min (2.75 gpm).

Well A-4 is completed to a depth of 48m (158 feet) through 20m (67 feet) of clayey sand and gravel allu-

vium, 20 to 42m (67 to 137 feet) of clay-rich sandstone and conglomerate and 42 to 48m (137 to 158 feet) conglomerate and coarse sandstone. Casing is 19cm (4-inch) PVC, with commercial saw-cut perforations from 42 to 48m (138 to 157 feet) and a bentonite annular seal at 41m (135 feet). Well A-4, with static water at 16m (52 feet), was pumped at 13 liters/min (3.5 gpm).

Well A-5 was sampled by bailer and later a pumped sample was collected. This well is 107m (351 feet) in total depth, is cased with 10cm (4-inch) PVC with perforation cuts between 98 and 107m (321 to 351 feet) and has an annular bentonite seal at approximately 66m (200 feet). Static water level was 96m (315 feet). This well monitors alluvial conglomerate beneath a tailings pile.

Geochemical Factors

Although the water standing in well casing may have originally come from the formation, various chemical reactions can take place in the casing that will substantially alter the nature of the water. The most important factor that affects the water chemistry is contact with atmospheric gases, most notably oxygen and carbon dioxide. Dissolution of these gases at a greater concentration than found in the formation environment changes the pH and oxidation conditions of the water.

Carbon dioxide dissolution or outgassing and pH readjustment can occur very rapidly in water. Some sampling procedures recommend pH field readings be performed in close chambers, before pumped water has had any chance to contact the atmosphere. The pH of water that has been standing in a well for weeks or months must certainly be suspect when a few minutes exposure at the surface can cause a pH change.

In general, metals are more soluble in acidic water, so a rise in the pH can cause some dissolved metal species to precipitate; or a decrease in pH can cause metals near the casing to be mobilized. In either case, water that has had time to establish equilibrium with atmospheric gases is not likely to be representative of the water chemistry in the formation.

Another important chemical change that standing well water can undergo is related to its oxidation potential. Usually, ground water in its subsurface environment comes into contact with only limited sources of free oxygen or other oxidizing agents. The resultant reduced ion species are likely to be oxidized when exposed to atmospheric oxygen. The most notable example of this behavior is ferrous iron. The green color of ferrous iron is common in well drilling when the reduced zone is reached. Formerly rusty sections of drill stem are often removed with a green/black coating. At a given pH, ferrous iron is more soluble than ferric, so oxidation often causes iron precipitation. The most common precipitation mechanism is the formation of ferric hydroxide.

As shown in reaction 1:

$$Fe^{2+} + 1/4\,O_2 + 2\text{-}1/2\,H_2O \rightarrow Fe(OH)_3 + 2\,H^+$$

the iron not only comes out of solution, but the pH of the solution is also affected. As Cherry et al. (1982) point out, this mechanism can have a very important effect in determining contaminant migration rates if sufficient oxidizing agent is available in the subsurface environment. They point out that sufficient free oxygen is rarely available in most aquifers to invoke the ferrous to ferric mechanism to a major extent. However, unlike native aquifer conditions, oxygen is usually available in monitoring well bores.

In addition to the acid contribution of the iron hydroxide precipitation reaction, the behavior of iron species has often been indicated as a very important factor related to heavy metal mobility. Coprecipitation of trace metals with the iron and adsorption mechanisms on iron hydroxide surface coatings have both been suggested to explain the iron-heavy metal interaction. Of course, any trace metals associated with the iron hydroxides would also be susceptible to remobilization because of Eh or pH changes affecting the hydroxide solubilities.

Results of Multiple Sampling

Figures 1 through 5 and Table 1 show field and laboratory results of the multiple samples collected for the various wells.

Prior to detailed descriptions and highlighting of notable trends found in the data, it is important to understand some complicating variations which are superimposed on the significant data. The most obvious source of parameter variability is normal laboratory precision limits, or in the case of the field data, variation due to equipment and operator precision. For example, field pH values, which can be read to 0.01 pH units, are reported only to the nearest 0.1 unit, a normally reliable field precision. Unfortunately, resources did not permit an extensive quality assurance program with multiple duplicates for strict statistical analysis of accuracy and confidence limits. In addition to the normal precision limits, minor variations in temperature have been noticed in response to ambient air temperatures or direct sun on hose rolled on the sampling trailer. A large amount of hose on the reel and a low pumping rate can cause a significant residence time in the hose at the surface. When this is the case, it appears that heat transfer in the hose can vary the temperature measured at the flow-through chamber by one-half to one degree C.

One of the most obvious characteristics of the sampling results is the lack of consistency of trends between wells. Note the difference between wells WC-1 and A-1 in relation to pH vs. specific conductance. As well WC-1 was pumped, both pH and specific conductance showed a marked decrease and then stabilized. In contrast, A-1 showed pH values that appear stable and then dropped to a new stable value after approximately five well-bore volumes were pumped. Conductivity values increased steadily. However, in each case, the laboratory parameters follow the field analysis trends quite closely. In well WC-1, iron concentration increased threefold and manganese twofold as the pH and specific conductance stabilized. In A-1, magnesium, sodium, chloride and sulfate followed the A-1 specific conductance increase. Zinc, the only heavy metal above detection limits in A-1, showed unpredictable variations; however, small variations this near the detection limits may be insignificant. Although trend directions are not the same in both wells, relatively stable field parameters appear to indicate stability of laboratory parameters. This is of particular interest because well WC-1 is a 2-inch well with a low pumping rate and A-1 is a 16-inch well pumped at 200 gpm.

Sampling in well WC-2 shows a well that stabilized relatively quickly, but produced some ambiguous field parameters. This is the sort of well that can cause sampler difficulty because one of the field parameters continued to drift as the well was pumped. The specific conductance gave a reasonable, or possibly slightly early, indication of the point at which the constituents had stabil-

Figure 5A. Well A-3 field parameters

Figure 5B. Well A-3 laboratory parameters

ised, but the pH drift continued even after laboratory parameters had stabilized.

Well A-2 is an example of a well that required purging, but was subsequently over-pumped sufficiently to mix in water of the much different quality. The field parameters were ambiguous in the early pumping; samples most representative of the aquifer were probably collected between five and 10 bore volumes. Most of the laboratory parameters had stabilized by that time (note calcium and aluminum), however heavy metals values were below detection limits. In contrast, notice the increase in specific conductance and variability of pH that marks later sampling, when mixing was occurring. Values of almost all parameters were affected by the new water that was being pulled into the well by extended pumping.

The effects of over-pumping can also be seen in the data from well A-3. In addition, A-3 data indicates water-quality zonation or stratification near the casing. A slug of water with low chloride, copper, magnesium, manganese, zinc and TDS values was drawn in at approximately two bore volumes and then followed by a slug of water with higher iron and copper concentrations. A complex interaction of two or more aquifers is likely in this case. Well log, completion and pump test data indicate that there may be a leaky aquiclude between the aquifer through which the well is screened and the overlying water-table aquifer. Also a zone surrounding the casing may have been altered by or mixed with drilling fluids. A large amount of water was injected when this well was rotary drilled. The last sample of the well indicates that a water with higher copper and aluminum, and lower pH sodium and sulfate was being mixed into the sample after extended pumping.

Table 1 (well A-5) shows the field and laboratory data from the well which was both bailed and pumped. The sampling personnel were aware of the need to purge wells when sampling with the bailer and the bailer was tripped into the well at least four times, after developing the well by air-lifting. The difference in laboratory and field data point out an extreme example of the misinformation possible when a well is not purged sufficiently before a sample is collected. Although the contamination of this aquifer under the tailings was hinted in the bailed sample, the pumped sample shows the true extent of the problem with pH 2.5 and contaminant concentrations of 35,112 mg/l TDS, 383 mg/l copper and 6,832 mg/l iron. Note that this water sample consists of 3.5 percent dissolved solids.

Discussion

The comparative sampling data presented here shows the need to understand the hydrologic regime into which a monitoring well has been installed.

Although it is important to purge water from wells before collecting a sample, over-pumping of complex regimes can cause mixing of water of different quality and, in the extreme case, contamination of non-contaminated aquifers by previously localized or stratified pollutants. The results indicate the importance of monitoring field parameters as pumping progresses. The number of bore volumes pumped provide an estimate of the amount to be purged before sampling, but is no substitute for real-time monitoring of field parameters to determine when samples are likely to be representative of the formation near the monitor well. Bailed samples or over-pumping are likely to result in grossly inaccurate monitoring data.

Rate of pumping can also be an important factor when related to the overall hydrologic regime. Mixing of aquifer water or induced leakage is much more likely if a large cone of depression is created by either a high rate of pumping or extended pumping. Well A-1 is an example of a well where a high pumping rate of 76.0 liter/min (200 gpm) was reasonable, because of a high well capacity. Again, the importance of understanding the hydrologic regime and well completion is apparent. A moderate pumping rate (8 parts/dash) important if multiple zone sampling is to be done in a well. The natural tendency for higher horizontal than vertical permeabilities will usually reduce the amount of interzonal mixing if a low pumping rate is utilized. A large amount of pumped water can also be a hazard if highly toxic contaminants are present. Excessive pumping can create a large volume of hazardous waste for disposal with no attendant increase in sampling accuracy.

Table 1
Well Data Analysis/Well A-5

Elevation M.P.	3,750 ft.
Total depth	351 ft.

Silicon dioxide	25.3	100
Aluminum	1.4	765

It would be convenient if stabilized field parameters would always indicate an accurate, representative monitoring well sample. However, as is apparent from the presented data, there are many factors which make sampling more complex. The results do indicate that the first water to be removed from the well is very unlikely to represent formation water quality. Variations in field parameters as pumping progresses will usually detect other parameter variations that must be interpreted in light of hydrogeologic and well completion information.

Biographical Sketches

Jim Rouse has an M.S. degree in hydrology from Stanford University and a Professional Degree in geological engineering from the Colorado School of Mines. He is president and general manager of Envirologic Systems Inc., serving the mining and waste disposal industries with baseline data collection, disposal impact mitigation, regulation advice, compliance monitoring and environmental permitting services. Previously, Rouse has had more than 16 years of experience with federal water pollution control agencies, the last seven years as the Environmental Protection Agency Mining and Milling Specialist.

Lee Wilson has an M.S. degree in geology from the University of Colorado and a B.A. in chemistry from Grinnell College. He is a geochemist and branch manager with Envirologic Systems Inc., consultant to mining, milling and waste disposal industries, providing hydrologic and geochemical services related to baseline monitoring, environmental permitting, compliance monitoring and environmental report preparation. Previously, Wilson has been a geology instructor at Angelo State University in San Angelo, Texas, and field geologist mapping oil shale in the Piceance Basin of Colorado.

A Laboratory Evaluation of Ground Water Sampling Mechanisms

by M.J. Barcelona, J.A. Helfrich, E.E. Garske and J.P. Gibb

Abstract

The reliability of ground water monitoring information can be assured by careful selection of sample handling and analytical procedures. Sampling mechanism selection has been studied far less than analytical methodologies (Scalf et al. 1981, Nacht 1983). This study has as its primary goal the identification of reliable sampling mechanisms for purgeable organic compounds and gas-sensitive chemical parameters in ground water. Carefully controlled sampling experiments were run to investigate the error contributed to chemical results due to sampling mechanism alone. Fourteen commercial sampling devices in five mechanistic categories were evaluated for their performance in sample collection for solution parameters, dissolved gases and purgeable organic compounds. Systematic errors related to sampling mechanism can reduce the accuracy of monitoring data by factors of two to three times that involved in analytical procedures.

Introduction

One of the principal obstacles to the reasoned management of ground water regulatory programs is the assurance of high quality reliable monitoring results. Research studies of subsurface processes share many of the same difficulties in sample collection and analysis. The ultimate utility of analytical results from monitoring or research efforts and the conclusions drawn from them depend heavily on the collection of representative samples.

Sampling procedures have been neglected over the years as sources of error in ground water work. Far more emphasis has been placed on analytical methodology, well design and construction. Since there now exist many sensitive, reliable protocols for the analysis of natural water samples for most chemical constituents, we are in a position to improve sampling methods based on known analytical benchmarks.

The reduction of systematic or determinate errors arising from biased sample handling procedures can be achieved when analytical interferences and materials' effects are known. These errors may yield both inaccurate, as well as imprecise results when unproven sampling protocols are used under field conditions. Systematic errors in sample handling stem from the physical and chemical disturbance of ground water solution composition during sample collection, preservation and storage prior to analysis. Field standards, spiked samples and blanks can be used to correct for errors that occur after the sample is brought to the surface. Only carefully controlled laboratory or field experiments can account for bias or imprecision due to sampling mechanism effects.

The need to sample ground water for specific chemical constituents under widely varying conditions demands that exhaustive testing of sampling mechanisms be conducted under carefully simulated or controlled conditions. The present study is an attempt to achieve this control for testing commercially available sampling devices. Operational performance characteristics of the sampling devices, master variables for ground water solution chemistry (e.g. pH, Eh, temperature and specific conductance) and dissolved volatile constituents are the main parameters of concern. Even if volative organic compounds or gases (O_2, N_2, CO_2, CH_4) are not of analytical interest, their loss from or introduction to a ground water sample can significantly affect solution chemistry and the speciation of other analytes. If sample collection causes the loss of soluble gases at the parts-per-million (ppm) level, the effect on trace constituents could be far more drastic. Since ground water samples are rarely in equilibrium with atmospheric gases, the disturbance of the sample matrix or background electrolyte must be minimized to collect analytical data that is representative of in situ conditions.

Experimental Design

The objective of this work was to identify faithful sampling mechanisms. We were primarily interested in comparing the relative magnitudes and causes of sampling bias or imprecision and those introduced in analytical methodologies.

Preliminary work in ground water sampling (Gibb et al. 1981, Schuller and Griffin 1981) has served to identify the general characteristics of a faithful sampling mechanism. They are detailed below:

1. The device should be simple to operate in order to minimize the possibility of operator error.

2. The device should be rugged, portable, cleanable and repairable in the field.

3. It should have good flow controllability to permit low flow rates ($\leq$100 mL·min^{-1}) for sampling volatile chemical constituents, as well as high flow rates (~1 L·min^{-1}) for large-volume samples and purging stored water from monitoring wells.

The mechanism should minimize the physical and chemical disturbance of ground water solution composition in order to avoid bias or imprecision in analytical results.

With these general characteristics in mind, a testing program was developed to permit the evaluation of commercially available sampling mechanisms. Fourteen commercial devices chosen for preliminary evaluation are shown in Table 1. They are representative of sampling devices in five mechanistic categories. Gas-lift devices employing rapid gas/water mixing and [illegible]ing and bubbling of water up and out of the well bore were not evaluated, as they have been documented as biased sampling mechanisms (Gibb et al. 1981, Schuller and Griffin 1981). Gas-lift mechanisms are clearly different from the gas-drive devices (e.g. Barcad®), which operate by a positive displacement mechanism with limited gas/water contact.

The evaluation was designed on a three-tiered structure shown schematically in Figure 1. The first level of testing consisted of a comparison of operational characteristics. The second level consisted of evaluating the performance of each operable device, both for the determination of the parameters indicative of well purging (pH, Eh, temperature and specific conductance) and the recovery of dissolved gases, e.g. CO_2, O_2, N_2, and CH_4.

Level 3 testing included the evaluation of sampling mechanism performance for the collection and analysis of specific compounds in the purgeable category of priority pollutants. Those devices that showed acceptable levels of performance in both Levels 1 and 2 entered Level 3 testing.

Level 1: Evaluation of Sampling Mechanism Operational Characteristics

The evaluation of sample collection mechanisms began with a critical comparison of the existing commercial designs using 14 criteria. These criteria and relative performance levels are shown in Table 2.

Each device was rated according to the criteria and the sum of all ratings was taken. Then the mean score

Figure 1. The three-tiered structure of the evaluation is shown here schematically

Table 1.
Sampling Mechanisms and Commercial Examples of Ground Water Monitoring Sampling Devices

Mechanism	Type	Commercial examples
Grab	Bailer	Homemade, TIMCO® (dual check-valve; bottom draw)
	Syringe	IEA Inc.
Positive displacement (bladder, non-gas contact)	"Middleburg" squeeze	IEA Inc. (Aquarius); QED Corp. (Well Wizard), Timco (GFP-TRV-2558)
	Bladder inflation	ISCO® (#2600)
Positive displacement (mechanical)	Helical rotor reciprocating diaphragm	Johnson Div. (UOP) — Keck, #SP-81 Bennett® (#180)
Gas displacement (gas contact)	Dedicated or pressure lysimeter type	Barcad® TIMCO® (GFP-TTVPLS-2474)
Other	Venturi suction (peristaltic)	ECO® (Samplifier) Masterflex® (#7570)

for all devices was calculated and the categories were rated as above-average or average-to-below-average on the basis of the score being either one standard deviation higher or within one standard deviation from the overall mean, respectively.

Determinations of flow rate output from the device over a range of head and lift conditions were the only actual measurements that went into this level of testing.

Level 2: Evaluation of Sampling Mechanism Effects on Solution Parameters and Gases

This level was designed to evaluate the range of utility of various sampling mechanisms. A reliable measure of the efficiency of well purging prior to sampling and the capability to collect unbiased samples for volatile constituents are important considerations for routine ground water monitoring.

Level 2 testing was conducted in a hydrologic test well facility, which allowed the circulation of a suitable background solution under controlled conditions (Figure 2). The testing system was designed to simulate conditions of 9.2m (30 feet) of lift at 5.0m (16 feet) of head above the sampler, conditions that are similar to many shallow ground water monitoring installations. The recirculating system incorporated a floating, lid-covered vat through which solution composition could be checked and adjusted. The background solution was dechlorinated Champaign, Illinois, municipal tap

Δ Calculated from average TDS, alkalinity and hardness, expressed in molar units.
** The relative standard deviation is the sample standard deviation from the mean expressed as a percent of the mean.

water amended by the introduction of O_2, CO_2 or CH_4, depending on the objectives of the specific experiment. The average background solution composition is detailed in Table 3.

The Level 2 test runs began by gentle sparging of an appropriate gas into the vat for a period of 30 to 45 minutes with the circulating pump in operation. (Carbon dioxide was used for pH adjustment (~7.5) in the runs for the indicator parameters, O_2, N_2 and alkalinity, while methane was used in supplemental testing for gas exchange and loss of volatiles). When in-line pH, Eh, temperature and specific conductance measurements stabilized (Garvis and Stuermer 1980), circulation was continued while water sampling was conducted.

The output of each operable device was sampled in triplicate during a minimum 15-minute period of operation. At the appropriate time, triplicate water samples were collected for O_2, N_2, CH_4 and alkalinity determinations, and a reading was taken for each of the solution parameters. Calibration standards and blanks for the gas determinations were prepared in triplicate at the beginning of the experimental period. Control samples were collected simultaneously with those from the devices via a sampling port in the well, which was at the same depth as the device under testing. Selected control samples were also taken from the vat to ensure that the recirculating solution was homogeneous.

Water samples for gases were collected by gently flowing the output from the device, well-sampling port or vat through the tip and out the top of a 20 mL polyethylene syringe. After the passage of several syringe volumes, the syringe plunger was replaced and all but 10.0 mL of the sample was forced out the tip through a three-way valve. This three-way valve permitted the introduction of 10.0 mL of helium headspace via a second syringe at atmospheric pressure. Once the sample and headspace had been vigorously agitated and allowed to equilibrate, the headspace was drawn back into the second syringe and the headspace sample was ready for analysis by gas chromatography (GC). Dissolved oxygen and nitrogen determinations were done by Winkler titrations (Carpenter 1965) and thermal conductivity GC, respectively; methane was determined by flame ionization GC (McAuliffe 1971).

Level 3: Recovery and Precision of Purgeable Organic Compound Sampling

Level 3 testing consisted of the analysis of water samples discharged from the sampling devices while they were operated in a closed system. Essentially the same lift and hydraulic head characteristics as in the Level 2 testing were maintained in this effort.

A schematic diagram of the closed-system test cell is shown in Figure 3. The sampling device was installed inside the 22-liter cell, which was constructed entirely of glass, aluminum and Teflon®. The background solution was spiked with four trihalomethane (THM) compounds (chloroform, bromodichloromethane, chlorodibromomethane and bromoform) and added to the test cell at a pressure of ~1.3 atm. The compounds were added in equal mixtures to give total THM's at levels from 80 to 8,000 ppb. The cell temperature was maintained at 15 C. Each device and associated tubing was flushed for at least five minutes. Sequential samples from the device under test were taken from the pumped flow at a height of approximately 40 feet (12.2m) above the cell while parallel control samples were taken from the cell. As in prior testing, triplicate samples were collected and each sample was analyzed in duplicate along with control samples, standards and system blanks according to EPA Method 601 (U.S. EPA 1982). Grab samplers that could not be operated in a totally closed system were tested through a larger opening in the test cell. Additional control samples were taken

before and after each of three grab samples for each device.

Results and Discussion

Level 1 Results: Operational Characteristics

The criteria used in the Level 1 testing (Table 2) are the essential attributes of an ideal sampling device. Accordingly, none of the existing designs was expected to merit a perfect score. This is indicative of the fact that no single type of device could be expected to provide representative samples under all conditions for a wide range of chemical constituents.

In this study, the conventional bottom check valve bailer received an average score. The remaining mechanisms were rated above-average or average-to-below-average, depending on whether the score fell at least one standard deviation above or within one standard deviation of the overall average, respectively. These results are shown in Table 4. The positive displacement bladder pumps, syringe sampler (grab mechanism) and gas displacement devices were rated above-average in probable performance. The other mechanisms were rated equal to or slightly below the bailer, since they were all within one standard deviation of the average. The order of the devices in the latter grouping has no particular significance.

The evaluation of the operational performance of the commercial samplers was instructive from two standpoints. First, very few of the devices have easily controllable flow rates for both volatile sampling and high rate well purging. In fact, several devices have a single high operational flow rate ($>2\ L \cdot min^{-1}$), roughly independent of lift or hydraulic head. Second, the operating instructions and general documentation of system operation, control and troubleshooting were inadequate in most cases. Given that there are a large number of monitoring installations that are serviced by relatively inexperienced technicians, the documentation could be improved substantially.

It is also noteworthy that at least half of the 14 devices evaluated failed to operate properly on delivery to the laboratory. In several cases, malfunctions (e.g. poor seals, leaky check valves) were observed when devices were operated in the transparent stand pipe.

Figure 3. A schematic diagram of the closed-system test cell

Since such problems may be difficult to diagnose and repair in field operations, it is important that all sampling gear be carefully checked out prior to use or installation. Minor repairs were conducted on several devices when possible in order to conduct further testing. At this point, 11 operationally reliable devices were considered for Level 2 testing.

Level 2 Results: Solution Parameters, Gas Exchange/Loss

In Level 2 testing, all devices were operated accord-

Table 4.
Sample Collection Mechanisms: Probable Operational Performance Characteristics as Measured by the Evaluation Criteria

Pump/device mechanism	Number evaluated	Category

* Categorization based upon performance that may be expected under "normal" field conditions and without extraordinary modification of commercial devices as represented by the preliminary performance evaluation criteria.

ing to manufacturers' specifications under the same conditions of head and lift.

Laboratory testing of ground water sampling mechanisms began with measurements of solution parameters indicative of the progress of well purging or flushing prior to sampling. The hydrologic test well was charged with background water (Table 3) and CO_2 gas was added to adjust the pH to 7.5-8.0. The water was then circulated through the test well to obtain initial readings of pH, alkalinity, specific conductance and temperature before the sampling device under examination was lowered into the well. Deviations from the background solution readings were observable to: ±0.01 (pH units), ±2 mv(Eh), ±5 μS (specific conductance) and ±0.1 C (temperature). A significant deviation from background levels was determined to be five times these observable differences.

The most sensitive parameters to the pumping mechanisms were pH and Eh. No significant deviations in specific conductance or temperature as a consequence of pumping were noted, although some heating did occur in long tubing bundles. This may be a problem in hot, sunny situations where transfer tubing is exposed to direct sunlight. Significant pH and Eh changes were observed for the peristaltic (suction) mechanism. Average changes of +0.05 pH units and -20 mv in Eh were noted for samples taken with this device. These are exactly the coincident changes one would expect if the mechanism encouraged degassing of CO_2 and O_2 in the pumped solution.

These results demonstrate the usefulness of most commercial sampling mechanisms for purging stagnant water from monitoring wells. This is true to the extent that our testing conditions simulate actual field conditions. With the exception of the peristaltic pump, adequate flow rates and the use of a less than ±10 percent change in the indicator parameters for complete purging are reasonable expectations from the pumping mechanisms.

Investigation of the potential for gas exchange with the atmosphere was conducted initially using high precision determinations of O_2 and CH_4. Oxygen runs were conducted in the 2 to 6 mg-$O_2 \cdot L^{-1}$ range, while methane levels varied from 0.1 to 18 mg-$CH_4 \cdot L^{-1}$.

Since the detection of significant mechanism-related error was made relative to the errors involved in both sample handling and analysis, it was important to establish the performance attainable for control samples (precision) and calibration standards (accuracy and precision). The accuracy (percent bias) and precision (percent relative standard deviation-RSD) for the controls are shown in Table 5. The average accuracy and precision for the calibration standards for both the oxygen and methane determinations were better than 10 percent. The fact that the control samples showed better precision than the calibration standards (made up by sequential dilution of saturated solutions) established that the test conditions were optimal to investigate the contribution of sampling mechanism to overall error.

The performance of 11 commercial devices in five mechanistic categories is shown in Tables 6 and 7. The accuracy of analytical results on water samples collected by the various mechanisms was uniformly poorer than that observed for the control samples. In most cases, the bias introduced into the analytical results fell in a range from -1 to 24 from the mean control values. This means that exchange or loss of gaseous solutes can be expected to cause false low values even in carefully collected ground water samples. The use of the positive displacement (no-gas contact) pumps (operated with air or N_2)and the grab mechanisms tended to minimize losses of oxygen and methane when carefully operated under controlled conditions. The gas displacement devices provided reasonably accurate results except with oxygen-sensitive constituents when air was used as the drive gas. Only the bladder pumps and the dual check valve, bottom-draw bailer sample results were not significantly different from the control mean values. This was a direct consequence of sampling precision (Table 7), which limited direct statistical tests (e.g. Student's "t" test) of mechanism-related errors. The data in Table 7 clearly show that the precision of samples collected by most of the devices was poorer by a factor of two or more than that of the control samples.

The Level 2 evaluation illustrated two major points. Inaccurate results (negative bias) can occur from sampling mechanism effects alone, which are two to three times higher than analytical bias. Poor precision arises from the actual operating conditions during sample collection. In this respect, the sampling mechanism and the expertise of the sampling technician are the major sources of imprecision. Critical variables are: time, temperature, reproducibility of flow rates and the technique of storage vessel filling.

On the basis of these results, two bladder pumps, both bailers, the peristaltic pump and the gas displacement devices were selected to undergo Level 3 testing.

Level 3 Results

Level 3 evaluations were conducted under closed-system conditions where the operation of the mechanism permitted. The bailers and syringe sampler were operated through the top of the system (Figure 3), while the peristaltic pump was operated at 12 feet (3.7m) of lift. All of the other pumping mechanisms were operated in the enclosed system pumping to a

∇ Bold entries denote significant differences were observed in more than half the experimental runs at the 95% confidence interval from Students "t" test.
Δ Overall accuracy cannot be reasonably assessed, since gross oxygen addition was observed in one run due to a check valve malfunction that resulted in a high positive average bias. Discounting this value, the overall accuracy was statistically identical to the conventional bailer results.

height of 40 feet (12.5m). Teflon transfer tubing was used to minimize materials' effects (Ho 1983; Barcelona, Gibb and Miller 1983).

Similar to the Level 2 testing, control samples were taken directly from the cell at intervals of five minutes, simultaneous with the pumped/collected samples. Calibration standards were made to ensure the integrity of sample handling and analytical steps throughout the study. The analytical performance data in Table 8 demonstrate that method performance for the four purgeable trihalomethane (THM) analyses was more than adequate to evaluate the effects of sampling mechanism-related errors. The accuracy and precision of both the calibration standards and control samples were better than 85 percent and five percent, respectively. THM compounds were used in equal concentration mixtures and the data analysis was conducted on each compound as well as total THM levels. Either mode of interpretation led to the same conclusions on sampling recovery and precision. Since analytical procedures and sample handling methods were identical for each mechanism and parallel control samples, mechanism-related error alone was isolated.

The accuracy and precision of the sampling runs for each mechanism at three levels of THM mixture concentration are shown in Table 9. Relative to the control samples, the positive displacement bladder pumps and the bailers showed no significant difference in accuracy or precision. Negative biases due to degassing and loss of volatiles in these results supported the conclusions of prior testing for O_2 and CH_4 recovery. With reference to the bailers, it should be noted that grab samples were taken directly from the reservoir and the samples were not subjected to the typical disturbance involved in retrieving the bailer from depth in a well bore. The results are indicative, therefore, of optimum sampling conditions and should not be considered typical of field performance. In general, the observed precision of the devices and control samples was sufficient to permit the treatment of the data by Student's "t" statistic. This was not the case in the Level 2 results where the variances were judged statistically different by the variance ratio (F) test.

Table 7.
Average Precision of Results From Device-Collected Samples Relative to Control Samples.

	Oxygen	Methane

Suction	4	1

Ratio of the relative standard deviation (RSD) of the samples from the devices to the RSD of the control samples.

The gas displacement and the peristaltic pump results clearly show that statistically significant losses of purgeable organic compounds can occur due to mechanism effects even under controlled sampling conditions. In most cases the bias worsened as the total concentration of THM's increased. The effects observed for the peristaltic (suction) mechanism are

further supported by the recent work of Ho (1983), who evaluated the effects of lift, concentration and materials on purgeable compound recoveries. He observed strongly negative biased recoveries ranging from 5 to 8 percent for THM compounds at lifts of 8 to 16 feet. These values are in excellent agreement with the value of 4.1 percent at 12 feet of lift observed in this study in the low concentration range. He further observed losses from 8 to 10 percent due to the use of silicone rubber transfer tubing as compared to Teflon®. It may be expected that ground water sampling for volative organic compounds with either gas displacement or suction mechanisms will introduce significant error into monitoring results. Figure 4 graphically depicts the relative magnitude of analytical and sampling bias observed in this study. Sampling mechanisms' effects under field conditions may be much greater, particularly for the conventional single check valve bailer, gas displacement and peristaltic devices. These devices demand very careful control of operating variables: agitation, pressurization/depressurization cycles, and pump speed, which complicate sample retrieval. Because this study was conducted at or below 25 C with low total dissolved solids (<200 $mg \cdot L^{-1}$) background solution, the results minimize the effects of temperature or the "salting-out" of volatile constituents (Friant and Suffet 1979). These observations underscore the need for careful selection of sampling mechanisms and methods in ground water monitoring efforts in order to ensure the reliable collection of representative samples.

In summary, the overall performance ranking of commercial sampling mechanisms is shown in Table 10 with recommendations for use. It is presented as a guide for planning comprehensive ground water data collection efforts. It should be reiterated that a careful evaluation of the information needs of the ground water monitoring program must be conducted prior to deciding on sampling mechanisms and protocols.

Conclusions

The task of obtaining representative samples of ground water in both research and compliance moni-

Figure 4. Graphic depiction of the relative magnitude of analytical and sampling bias observed in this study.

Table 10.
Performance Evaluation of Ground Water Sampling Mechanisms for Purgeable and Gas-Sensitive Parameters

Mechanism category	Overall performance ranking	Remarks
Positive displacement (bladder)	Above average	Expected to provide both efficient well purging and representative samples over a range of conditions with minimal difficulty in field operations.
Grab samplers		
conventional bailer	Average	Unsuitable for well purging; require very careful operation and sample handling precautions under field conditions; field performance open to question.
dual-check valve bailer	Average	
syringe pump	Average—below average	
Positive displacement (mechanical)	Average—below average	Suitable for well purging; sampling performance very dependent on specific design and operational details.
Gas displacement (gas drive; not gas lift)	Average—below average	May be suitable for well purging if used in conventional installations; malfunctions are difficult to assess or repair; significantly lower recoveries of purgeable organic compounds and gases may occur depending on field conditions and operator experience.
Suction	Below average	Suitable for well purging at depths to approximately 20 feet; significantly lower recoveries of purgeable organic compounds and gases will result from sampling with this mechanism.

toring programs must be carefully approached. Most pumping mechanisms may be expected to perform satisfactorily for well purging and the measurement of solution parameters. However, sampling for gas-sensitive and volatile chemical constituents can be significantly biased by degassing and loss of volatiles during sample collection.

Significant bias and poor precision may be expected in shallow ground water sampling with gas displacement, positive displacement mechanical, and suction mechanisms, unless extraordinary care is taken in sample retrieval, transfer and collection. Bladder (no-gas contact) pumps are superior for most applications. The performance of grab samplers, particularly bailers, is heavily dependent on both the expertise of sampling personnel and field conditions. The ideal controlled conditions under which these performance data were collected represent an optimum situation for the observance of minimal sampling error. Field conditions and solution composition are complicating factors that must be evaluated on a case by case basis.

Biographical Sketches

Michael J. Barcelona is currently the head of the Aquatic Chemistry Section of the Illinois State Water Survey. He has B.A. and M.S. degrees in chemistry and received a Ph.D. in marine chemistry in 1977. For the past five years he has been involved in research on critical sampling and analytical considerations for organic geochemical studies in natural water.

John A. Helfrich is an assistant professional scientist in the Aquatic Chemistry Section of the Survey. He has a B.S. degree in biology and received an M.S. degree in water chemistry in 1982 from the University of Wisconsin-Madison.

Edward E. Garske is an assistant supportive scientist in the Aquatic Chemistry Section of the Survey. He received his B.S. degree in water chemistry from the University of Wisconsin, Stevens Point, in 1979.

James P. Gibb is the head of the Ground Water Section of the Survey. He has more than 20 years experience in both ground water research and resource assessment investigations and has authored many scientific publications on these topics. He received a B.S. degree in civil engineering from the University of Illinois in 1966.

Stainless Steel Pipe and Screens

- Stainless steel provides strength, long life and minimum interference with sample analyses.
- Continuous slot construction produces high open area. Higher volume of water can be drawn in a shorter length of screen which allows more representative sampling.
- Flush joints between screen and pipe lengths mean sampling devices won't hang up inside. Gravel pack and backfill won't bridge outside.
- Screens and pipe available in various lengths and 6 diameters.
- Locking cap available for protection of the well.

Stainless Steel Pipe

PIPE SIZE	PIPE DIAMETER		SHIP WT (lb/ft)	PRICE (INCLUDES END FITTINGS)				ADDITIONAL PIPE (per ft)
	O.D. (IN.)	I.D. (IN.)		3 FT	5 FT	10 FT	20 FT

3 inch	3.500	3.068	3.1	61.40	82.90	136.65	244.15	10.75
4 inch	4.500	4.026	4.0	79.55	108.75	181.75	327.75	14.60
5 inch	5.563	5.047	6.5	130.50	171.30	273.30	477.30	20.40
6 inch	6.625	6.065	7.7	168.00	225.00	367.50	652.50	28.50

Stainless Steel Screen

SCREEN SIZE	SCREEN DIAMETER		SHIP WT (lb/ft)	PRICE (INCLUDES END FITTINGS)					ADDITIONAL SCREEN (per ft)
	O.D. (IN.)	I.D. (IN.)		2FT	3 FT	4 FT	5 FT	10 FT	
1¼ inch	1.660	1.130	3.0	$ 59.35	$ 77.95	$ 96.55	$115.15	$208.15	$18.60
2 inch	2.370	1.800	4.0	78.80	104.90	131.00	157.10	287.60	26.10
3 inch	3.500	2.970	5.0	87.75	117.05	146.35	175.65	322.15	29.30
4 inch	4.500	3.985	6.0	117.95	159.05	200.15	241.25	446.75	41.10
5 inch	5.563	5.000	7.5	165.10	213.00	260.90	308.80	548.30	47.90
6 inch	6.625	6.065	9.0	189.60	243.15	296.70	350.25	618.00	53.55

IMPORTANT NOTE: Pipe and screen lengths shown do not include length of fittings. Pipe fittings are Johnson flush thread female top and male bottom. Screens have female flush thread top and stainless steel point bottom on 1¼" and 2" size; stainless steel flat plate bottom on 3-6" sizes.
TO PRICE UNLISTED LENGTHS: Add appropriate "per foot" price to nearest listed length. For example, an 8-ft length of 2-inch diameter pipe is $56.60 plus 3 x $6.00 = $74.60 total.

Stainless Steel Locking Cap (U.S. PAT. NO. 4376619)

PART NUMBER	CAP SIZE	PRICE
6200351	1¼"	$22.50
6200352	2"	27.50
6200353	3"	32.50
6200354	4"	37.50
6200355	5"	43.00
6200356	6"	49.00

These prices are for the locking cap with the locking lug welded to that cap. The compatible locking lug is welded to the top section of stainless steel pipe in each well. On the pipe we substitute the female threaded end fitting with the locking lug with no change in pricing. If customers wish to adapt their own pipe, the locking lug is available separately for $4.50.

PVC Plastic Pipe and Screens

- Sonic welded PVC produces high strength screen.
- Sonic welded PVC wire-wrapped screen has high strength and more open area per given slot size than any other non-metallic screen available.
- Resists corrosion from salts and gases commonly found in either fresh or salt waters.
- Precision slot openings available in sizes from 0.006 inches on up.
- The only continuous slot non-metallic screen available without a restricting pipe base.
- Thermally attached fittings eliminate need for joining solvents.
- Screens and pipe are available in 6 diameters and various lengths.
- PVC thread is compatible with SS thread.
- SS locking cap assembly can be used with PVC.

PVC Pipe

PIPE SIZE	PIPE DIAMETER		SHIP WT (lb/ft)	PRICE (INCLUDES END FITTINGS)				ADDITIONAL PIPE (per ft)

Johnson screens by UOP

Johnson-Petur™ Water Level Monitoring Systems

Designed for accurate water well pumping tests and for aquifer testing with observation wells.

- Senses water level from pneumatic piezometer or bubbler tube.
- Two sensing channels in readout instrument.
- Eight additional sensing channels with pneumatic multiplexer.
- Programmable for metric or English units.
- Pre-programmed, automatic sequential readouts for time and water level changes.
- Reprogrammable for other time and water level changes.
- Standard pressure range is 0-100 psi (231 ft)—other ranges available on request.
- Strip chart data recording.
- RS232 serial data port to interface with other outside recording devices.
- Power supply is rechargeable Ni-Cad battery and/or external 12v DC source such as vehicle battery.
- Self-contained gas supply tank plus external connections for CO_2 or N_2.
- LCD data display independent of strip chart printer.
- Time data is in minutes and tenths of minutes.
- Pressure data is in psi, ft of H_2O or meters of H_2O.
- Optimum temperature range -4F to 176F (-20C to 80C).
- Accuracy at 0 - 115 ft is 0.1% (0.12 ft)
  0 - 231 ft is 0.35% (0.80 ft)
- Sensitivity at 0 - 115 ft is 0.0022% (0.003 ft)
  0 - 231 ft is 0.0112% (0.03 ft)

C-300-2 MULTIPLEXER

Standard 8-channel pneumatic multiplexer connects to the C-108 Controller. Unit includes airlines and electrical wire to make connection.

$2,655.00

C-108 CONTROLLER-READOUT

Gives readout of water levels measured by pneumatic sensors. Programmable for either metric or English units, timing of automatic sequential readouts and given waterlevel changes. Standard pressure range of 0-100 psi. Unit includes rechargeable Ni-Cad battery and recharger, and tank connectors and supply airlines for CO_2 or N supply. Also included is 1,000 ft of 3/16-inch O.D. nylon surface airline tubing and instruction book.

$5,820.00

Extra tubing for surface airline, 1,000 ft roll

$80.00

C-28 PRINTER

Electrostatic printer connects to the C-108 Controller. Electrical connecting wire and paper included.

$1,830.00

Shipping Box holds one, two or all three Johnson-Petur™ components. Price is $150.00. On return of the shipping box, freight paid, $100 will be refunded.

ALL UNITS SHIPPED FOB ST. PAUL, MN.
SHIP WEIGHT: 100 LBS.

Johnson-Keck® Model SP-81 Submersible Sampling Pump

Designed for use in 2-inch diameter monitoring wells, the SP-81 is made of essentially chemically inert materials. Easily cleaned and reused, it operates by rechargeable battery at remote sites. Produces uniform, continuous flow. No special tools needed for on-site cleaning or repair.

Specifications

Pump outside diameter: 1.75 inches
Pump length: 25.0 inches
Pump weight*: 8 lbs.
Power: 12 volts DC at 10 amps
Capacity: 0.6 gpm at 125 ft head
1.2 gpm at 10 ft head
Operating temperature: -20C to 38C
Pressure: 120 psi (Refer to the pumping curve for other minimal operating ranges.)
RPM: 500

*Weight does not include power cable, discharge tubing or battery pack.

Standard Equipment

PUMP:
- Positive displacement
- 304 stainless steel pump housing
- EPDM synthetic rubber stator
- 316 stainless steel rotor
- DC motor housing is 304 stainless steel
- Electrical terminations are Teflon† and 304 stainless steel
- 3/8-inch 304 stainless steel barb discharge tubing connector

BATTERY PACK:
- Weight 25 lbs.
- 12-volt DC rechargeable by AC or DC
- Forward/off/reverse switch
- Voltage and current monitoring display
- Thermal auto-off circuit breaker
- DC power cable
- AC power cable

POWER CABLE:
- 125 feet long
- Teflon sheathed
- 10-gauge, 2-connector serves as pump lowering wire
- 750 lb. breaking strength

DISCHARGE TUBING:
- 125 feet long
- Bev-A-Line Type X polypropylene

Optional Equipment
Viton stator
Teflon discharge tubing
Cable tubing storage reel
Inflatable packers (2-in. or 4-in.)
Cable clamp to suspend pump
Auto battery monitor

†Teflon is a registered trademark of Du Pont Inc

STANDARD UNIT	Includes complete pump with EPDM stator, battery back, power cable, Bev-A-Line X discharge tubing, cable clamp and shipping crate	$3,900.00
OPTIONAL UNIT	Includes complete pump with Viton stator, battery pack, power cable, Teflon discharge tubing, cable clamp and shipping crate	$4,330.00

- All units & accessories shipped FOB St. Paul, MN or East Lansing, Mich.
- Standard unit in shipping crate is approximately 100 lbs.

Stainless Steel Bailer Water Sampler

Designed especially for obtaining water samples from small diameter monitoring wells, these samplers are made of type 304 stainless steel. Check valve is all Teflon material. All sizes shown are in stock for immediate shipment.

Teflon Bailer Water Sampler

Made completely of Teflon† to assure integrity of water samples, the bailer has removable molded ends for thorough, easy cleaning. The sampler has a built-in check valve and lifting hook. Not illustrated.

†Teflon is a reg. TM of DuPont Corp

SERIES II PERISTALTIC PUMP

3699

The GeoFilter Series II Peristaltic Pump was designed for multistation pressure or vacuum pumping for liquids or gases in or out of the laboratory. This unit is ideally suited for sample removal from shallow wells. They are compact, measuring 3½" X 8½" X 8, and are constructed from heavy gauge anodized aluminum which provides durability and corrosion resistance without excess weight. The unit operates at 300 and 600 RPM individually and simultaneously, and is capable of pumping 500 milliliters per minute from the 300 station, and 1000 milliliters per minute from the 600 station. The complete unit comes with the GeoFilter Peristaltic pump, one Masterflex 7015 pump head, Samsonite carrying case, and 5' of silicon tubing.

ORDERING INFORMATION	ORDER NUMBER
12 Volt DC, 300 and 600 RPM variable speed pump with pump head, carrying case, silicon tubing, and 10' power cord with battery terminal clips, or cigarette lighter adaptor.	0710
115 Volt AC, 300 and 600 RMP variable speed pump with carrying case, silicon tubing, and 6' power cord with grounded AC plug.	0730
12 Volt DC and 115 Volt AC, 300 and 600 RPM variable spped pump with pump head, carrying case, silicon tubing, and two power cords, a 10' with battery terminal clips or cigarette lighter adaptor, and a 6' with grounded AC plug.	0760
Add-on Pump head, mounts directly to the face of existing pump head.	5701
Additional 7015 pump head, standard with unit.	5702
F.D.A. approved silicon tubing.	5703

Masterflex-Registered TM of Cole-Parmer Instrument Co.

ISCO's new battery-operated Portable Pump for shallow lift liquid sampling

Specifications

PHYSICAL SIZE:	Height: 11 in. (28cm) Width: 9 in. (23cm) Depth: 9 in. (23cm)
WEIGHT:	8 lbs. (3.6kg)
POWER REQUIREMENTS:	12 VDC
CURRENT CONSUMPTION:	2.5 amps, typical
OVERCURRENT PROTECTION:	5 amp slow blow fuse
SUCTION LIFT:	26 ft. (7.9m) maximum
PUMP RATE (3' of head):	1/4" I.D. suction tube: 2400 ml/min 3/8" I.D. suction tube: 3000 ml/min
LINE TRANSPORT VELOCITY: (3' of head)	1/4" I.D. suction tube: 4.1 ft/sec 3/8" I.D. suction tube. 2.1 ft/sec
AMBIENT TEMPERATURE RANGE:	32° to 120°F (0° to 49°C)

ISCO's new Portable Pump is specifically designed to sample shallow test wells with up to 26 feet of lift. The pump is also suitable for collecting samples from a variety of other sources, such as sewers, streams, lakes, etc.

Field-proven reliable

The rugged unit utilizes the same proven peristaltic pump system found in ISCO's wastewater samplers. All controls and the pump drive mechanism are housed in a water-tight, structural foam plastic case.

Non-contaminating

Pumped straight from source to bottle, the sample contacts only the Teflon* or vinyl suction line, the polypropylene and stainless steel inlet strainer (use optional), the medical-grade silicone rubber pump tubing, and a glass or plastic sample container. Samples do not contact any part of the pump mechanism. Cleaning the system is easily accomplished by reversing the pump, purging with distilled water or the next sample, or replacing relatively inexpensive lengths of tubing.

Easy to use

The compact Portable Pump can be powered by a rechargeable Nicad battery (may be mounted internally), a 12 VDC automotive battery, or a 117 VAC power converter. Pump action is controlled simply by setting a three-position manual switch to "FORWARD," "OFF," or "REVERSE." Ambient operating temperatures range from 32° to 120° in weather conditions including rain or dust.

* DuPont

Ordering information

For each complete Portable Pump, you must specify the pump, a power source, suction line, and sample container.

Portable Pump, without power source 60-3004-060

POWER SOURCES

Nicad Battery, without charger. Installs inside the control unit 60-1684-040
Battery charger only. To recharge internally mounted Nicad Battery 60-3004-070
AC Power Converter/Battery Charger, 117 VAC, 50/60 HZ to operate pump from 117 VAC. May also be used with connect cable below to recharge internally mounted Nicad Battery, or without cable below, may be used to recharge external Nicad Battery 60-1684-088
Same, except 234 VAC, 50/60 HZ 60-1684-093
Connect Cable, Portable Pump to power converter, for recharging internally mounted Nicad Battery 60-3004-068
Connect Cable, Portable Pump to external automotive type battery 60-1394-023

SUCTION LINES, STRAINERS

1/4" I.D. x 22' vinyl suction line with weighted polypropylene bodied strainer 60-1394-054
3/8" I.D. x 20' vinyl suction line with weighted polypropylene bodied strainer 60-1684-035
3/8" I.D. x 10' Teflon® suction line, Neoprene® rubber protective coating, without strainer 60-1683-146
Same, except 20' length 60-1683-144
Weighted strainer only, 3/8", all stainless steel 60-1684-110
Teflon® suction line flaring tool, to allow insertion of above strainer 60-2103-093
Bulk 1/4" I.D. vinyl tubing, 100', without strainer 68-1680-055
Same, except 500' 68-1680-056
Same, except 1000' 68-1680-057
Bulk 3/8" I.D. vinyl tubing, 100', without strainer 68-1680-058
Same, except 500' 68-1680-059
Weighted strainer only, 1/4" polypropylene body 60-1394-070
Weighted strainer only, 3/8" polypropylene body 60-1394-071
Extra silicone rubber pump tubing, 33" length 60-2104-054
Bulk silicone rubber pump tubing, 15' length 68-1680-061

SAMPLE CONTAINERS

1/2 gallon polyethylene bottle with cap 68-2600-002
1/2 gallon glass bottle with cap 68-2600-003
2 1/2 gallon polyethylene sample container with cap 299-0013-04
2 1/2 gallon glass bottle with cap 291-0000-00
3 gallon polyethylene sample container with cap 299-0013-02
5 gallon polyethylene sample container with cap 299-0013-01

MARTEK® MARK V DIGITAL WATER QUALITY ANALYZER

MARTEK INSTRUMENTS, INC. MANUFACTURERS OF ENVIRONMENTAL INSTRUMENTATION

. . . low cost multi-parameter field or laboratory water quality analyzer

DESIGN AND PERFORMANCE FEATURES

- Direct in situ measurements of temperature, conductivity, dissolved oxygen, and pH to depths of 300 meters.
- Automatic temperature compensation for dissolved oxygen and pH.
- Digital display with simultaneous four parameter recorder output signals.
- AC or DC power operation with internal rechargeable batteries.
- Operates in very low temperature (−30°C or −22°F) and rugged environment.
- Better than ±1.0% overall measuring accuracy.
- Simple to operate and calibrate.

DESCRIPTION

The Mark V Water Quality Analyzer is a four parameter digital analyzer that provides optimum efficiency for accurately measuring the basic physical and chemical properties of coastal, inland, and ocean waters. The unit is designed to measure in situ temperature, conductivity, dissolved oxygen, and pH to depths of 300 meters (1000 feet) with automatic temperature compensation for pH and dissolved oxygen. A regulated AC/DC power supply unit contained in the instrument case offers optional operation from internal rechargeable batteries, AC, or external +12 volts DC power sources. Simultaneous recorder output signals are provided for all four parameters for telemetering or on-site recording of data. Individual parameter signals may be directly read out on digital display through a selector switch.

The Mark V Digital Water Quality Analyzer System is a general-purpose, multi-parameter measuring instrument suitable for intermittent or permanent use when making in-situ, vertical-profile, and remote unattended long term surveys at selected sites. It is specifically adaptable to projects requiring continuous, stationary operation from fixed shore stations, or for profiling surveys in shallow water depths to 300 meters (1000 feet). Moreover, through the utilization of MIL SPEC components, the instrument can operate in extremely low temperature environments (−30°C or −22°F) without affecting the quality of measurement. Standard measuring ranges offered for the various parameters meet most fresh and salt water conditions. The operation, maintenance, and calibration of the instrument are designed for use by personnel with a minimum of instrumentation experience, yet yield laboratory accurate data of better than ±1.0%.

APPLICATIONS

The Mark V is designed to provide easy-to-read digital parameter data for laboratory and field applications. Its unique circuitry permits digital operation under remote rugged field environments where AC power may not be available. It is ideal for sophisticated measurements of water samples of either fresh or salt water bodies. It is an efficient and reliable instrument for providing portable spot-tests, and long term measurement of water samples aboard floating laboratories, in water treatment and waste water facilities; and for in situ measurements of water bodies such as rivers, reservoirs, ponds, lakes, coastal and inland waters, and sewage and industrial plant effluents.

MARK V SPECIFICATIONS

MEASUREMENT PARAMETERS	RANGE	ACCURACY	RESOLUTION	SENSOR TYPE
Temperature	−5 to 45°C	±0.1°C	0.01°C	Thermolinear array
Conductivity	0-1000 micromhos/cm or	±10.0 micromhos/cm	1.0 micromhos/cm	Platinized nickel Electrodes
	0-100 millimhos/cm	±1.0 millimhos/cm	0.1 millimhos/cm	
Dissolved Oxygen	0-20 ppm (mg/liter)	±0.1 ppm	0.01 ppm	Polargraphic gold/silver electrode system; automatic temperature compensation and in situ stirrer.
pH	0-14 pH	±0.1 pH	0.01pH	Combination pH electrode with silver-silver chloride reference internals mounted in plastic housing; automatic temperature compensation.

SYSTEM PERFORMANCE

SENSOR ASSEMBLY

Housing: Hard-anodized aluminum and PVC plastic.

Dimension: Overall 4.5 inches (11.5 cm) diameter by 19 inches (48.3 cm) length

Weight: 8.0 pounds (3.6 Kg)

Cable: 0.32 inches (0.81 cm) diameter and (0.1 lb per foot) (0.15 kilograms per meter).

DATA READOUT:

Controls:

A. Power Switch
1. OFF
2. ON – Turns power ON to digital display DPM.
3. DIM – DPM digital display flashes seven times per second to conserve battery power; recorder signal output available for four parameter simultaneous recording.
4. BLANK – DPM digital display meter is off, but instrument is still on permitting continuous recorder monitoring. This setting provides maximum battery conservation.
5. CHARGE – Connects charging circuit to internal rechargeable batteries.

B. Function Switch
1. BATTERY – Measures battery voltage to determine if the batteries require recharging.
2. TEMP., COND., DO., pH – Selected parameter id displayed on DPM digital display.

Dimension: 6.4 inches (16.3 cm) high x 11.1 inches (28.2 cm) wide by 11.3 inches (28.7 cm) deep.

Weight: 15 pounds (7.0 kg) net weight
16 pounds (7.5kg) shipping weight

POWER SUPPLY:

Regulated self-contained internal rechargeable battery pack with built-in charging circuit external + 10-14 volts DC, or 105-125 VAC (210-250 VAC), 50/60 Hz.

RECORDER OUTPUT:

0-1 volts DC analog full scale for each of the four parameters.

ENVIRONMENTAL CONDITIONS

Temperature Effects: −30°C to 38°C (−22°F to 100°F) operation and storage (accurate performance of sensors and batteries are affected below 0°C temperature operation).

Moisture: Gasketed, splashproof construction throughout.

Corrosion: Aluminum control panel and carrying case prepared and coated to MIL specs for maximum corrosion resistance in the marine environment.

ORDERING INFORMATION

PART NUMBER DESCRIPTION

166 Model Mark V Water Quality Analyzer, includes:
a) 166-10 Data Readout Module
b) 166-20 Sensor assembly for temperature, conductivity, dissolved oxygen with stirrer and pH probes.
c) Cable Assembly
d) 166-50 Detachable lids with storage compartments for power cable, two solution bottles for pH buffers, DO membrane and electrolyte kit, and screwdriver.

Note: Specify 115 volts or 230 volts, 50/60 Hz

NOTE: All pricing F.O.B. Irvine, California including 12-month product warranty against defects in material and workmanship. Prices and specifications subject to change without notice.

MARTEK INSTRUMENTS, INC. MANUFACTURERS OF ENVIRONMENTAL INSTRUMENTATION

MEASUREMENT SYSTEMS

Mark IX Process Water Quality Monitoring System

The Mark IX Process Water Quality Monitoring System may be operated in conjunction with other members of the Martek instrumentation family to produce a fully automated monitoring and control system with features such as video display of sensor data; formatted hard copy printouts; micro-programmed data acquisition; and recording and control of desired parameters. The Mark IX offers a combination of practicality and economy for large scale monitoring or control situations. A 64-channel signal conditioning unit utilizes a built-in multiplexer; provision for up to eight multi-sensor plug-in signal conditioning printed circuit boards; on-board drivers for up to 12 flow sensors; and easy sensor hook-up terminal strip. The unit has a flexible motherboard design which permits a wide variety of sensor configurations featuring all of Martek's popular sensors. As many as four 64-channel signal conditioning units may be utilized in a system completely controlled by the Martek Model DMP Data Microprocessor/Controller.

Mark VII Digital Water Quality Analyzer/Controller

The Mark VII Digital Water Quality Analyzer/Controller is designed to provide flexibility and efficiency for accurate measurement of the basic physical and chemical properties of coastal, inland, and ocean waters to depths of 300 meters. Specific parameter sensors and their related signal-conditioning plug-in printed circuit boards can be omitted or added depending on the user's field requirements. The user can select up to four parameters including multiple single parameters from the following available measurements: temperature, conductivity, salinity or temperature-corrected conductivity, depth, dissolved oxygen, pH specific ions, and turbidity. A regulated AC/DC power supply unit contained in the instrument case offers optional operation from internal rechargeable batteries, AC, or external 12-volt DC power sources. Simultaneous recorder output signals are provided for all four parameters as well as battery voltage for telemetering or onsite recording of data. Individual parameter signals may be directly read out on the digital display through a selector switch. Through the optional use of plug-in printed circuit boards, the Mark VII can also serve as a controller for any given two parameters monitored by the analyzer.

Mark VI Water Quality Monitor

The Mark VI Water Quality Monitor is similar to the Mark V configuration, but it represents a more sophisticated and expanded instrument. The Mark VI monitors seven parameters: temperature, conductivity, salinity or temperature-corrected conductivity, dissolved oxygen, pH, depth, and optional ion selective electrode to depths of 300 meters. It features a five-element conductivity sensor which permits operation in fresh or sea water bodies without changing the sensor. The unit can operate on internal rechargeable batteries, AC or external DC power. All calibration adjustments, including reference voltage adjustments, are easily made and accessible through the front panel. Like the Mark V, the Mark VI features a single digital panel meter for readout of individual parameters via a selector switch while providing simultaneous recorder output signals for all parameters regardless of the selector switch position.

Mark X Water Quality Monitor

The Mark X is an in situ self-contained system for measuring tempurature, pH, conductivity, and temperature corrected conductivity or salinity in the field or in the laboratory. The standard configuration, including the readout module, weighs less than 6 pounds (2.7 kg); thus facilitating field monitoring under rugged environmental conditions. It can operate throughout the standard conductivity range of fresh to sea water samples without altering the conductivity sensor.

MEASUREMENT SYSTEMS

Model SCT Soil Conductivity And Temperature Monitoring System

The Model SCT is an in situ system for measuring soil conductivity and temperature, which are utilized for calculating soil salinity. The unit provides an accurate method of determining the changes in salinity caused by seepage, irrigation or other influences. For convenience, the conductivity is corrected to 25°C which provides the soil scientist with a useful number without conversion. The Model SCT readout module incorporates a four digit liquid crystal display, a battery power supply, switch controls, and front panel access to calibration controls. The battery power supply is rechargeable with the charger provided for the system.

Model XMS In Situ Transmissometer

The Model XMS In Situ Transmissometer is a portable, research-quality instrument specifically designed for optimum underwater measurements of turbidity by determining the percent transmission of a light beam through a known pathlength in the water. It provides high accuracy, ± 1.0% over a wide alpha measurement range (0.1 to 4.6 meter for one meter pathlength). Readout of the light transmittance measurement is obtained instantaneously on a high resolution digital panel meter. A recorder output permits onsite or telemetry recording. Continuous records of percent transmission versus temperature and/or depth may be obtained by using optional plug-in signal conditioning printed circuit boards and sensors. The Model XMS separate power supply permits operation from either internal rechargeable batteries, external 12 volts DC, or 105-125, 210-250 VAC, 50/60 Hz. The one meter cell path underwater sensor can be used in either turbid or clear water without altering the cell path of the sensor to depths of 300 meters. For very turbid measurements, a 25 cm cell path sensor is available.

Mark V Water Quality Analyzer

The Mark V Water Quality Analyzer is a low cost four parameter digital analyzer designed to provide economical field measurement of temperature, conductivity, dissolved oxygen, and pH in fresh and salt water bodies to depths of 300 meters. A regulated AC/DC power supply unit contained in the instrument case offers optional operation from internal rechargeable batteries, AC, or external DC power sources. Individual parameter signals may be directly read out on the digital display through a selector switch, while simultaneous recorder output signals are provided for all four parameters.

Mark XI Digital Process Monitor/Controller

The Mark XI Digital Process Monitor/Controller is designed to monitor and control either pH or conductivity. Temperature circuitry is standard and may be monitored by simply adding the sensor. The Mark XI contains a display selector switch which permits the user to view the pH or conductivity value, temperature, plus low and high set-points values from the optional controller board. Both 0-1 volt DC and 4-20 ma milliamp outputs are available. The optional controller is plug-in compatible and offers two single pole, double throw relays for peripheral control. The relays may be operated in either a simple "ON-OFF" mode or a "TIMED RESET" mode. The "TIMED RESET" period is adjustable from one to five minutes.

Mark VIII Water Quality Data Logger

The Mark VIII Water Quality Data Logger is a combination analyzer and data logger packaged in a single case. It provides direct field *in situ* measurements of temperature, conductivity, salinity, dissolved oxygen, pH and depth; or multiple single parameter sensors to depths of 300 meters. Specific parameter sensors and their related signal conditioning plug-in circuit boards can be omitted or added depending on the user's field requirements. While the parameters are being read out on the digital display, the signals are recorded on a magnetic tape cassette. The logger accepts up to 14 data channels with day and time recorded with each scan of data. The ID switch may be used to identify 1000 locations. The Mark VIII can operate in manual, continuous, or program mode, thus providing flexibility as well as facilitating the accumulation and processing of field data.

Mark XV Water Quality Microprocessor

The Mark XV Water Quality Microprocessor is designed to measure *in situ* seven parameters of temperature, salinity or temperature corrected conductivity, depth, dissolved oxygen, pH and optional selective ions as a function of depth with automatic temperature compensation for all parameters. System calibration for all sensors is controlled by the low power, CMOS, microprocessor. All screw-driver adjustments have been eliminated. Calibration is performed digitally with calculated factors being stored in non-volatile RAM. The alphanumeric display allows any two parameters to be displayed simultaneously. For data recording purposes, the Mark XV is equipped with a serial ASCII, RS232 port for compatibility with computer peripheral equipment. Sensor data along with date and time of day may be transmitted to this port at anytime under operator control. This serial data may be used to drive external telemetry equipment or to provide a local print-out. The conductivity measurement is unique by providing auto ranging for the solution being monitored. Two ranges, 0-9.999 millimho/cm or 0-99.99 millimhos/cm are automatically selected according to the value of the sample. The displayed conductivity reading is temperature corrected between 0 to 50°C and in certain instances may be calibrated in salinity units.

Model PEW Portable Environmental Winch

The Model PEW Portable Environmental Winch has been designed to facilitate cable handling and to record multi-parameter water quality data during descent and ascent for any type of profiling or monitoring requirements. The winch is a compact, rugged unit capable of operation in the marine environment. It is supplied with 25 slip rings which permit operation with the Martek Water Quality Analyzers, or the Model XMS *in situ* Transmissometer. The Model PEW can handle cable capacity up to 300 meters (1,000 feet). The unit is available with an electric motor drive.

DAS Series Data Acquisition System

The DAS Series Data Acquisition System is an economical and extremely flexible data system designed to meet a wide range of applications, from stand-alone environmental data loggers to industrial monitors. The system is comprised of a multitude of independent modules that can be arranged in various configurations to meet each specific application. All data acquisition parts of the system are built from advanced logic circuitry (COS/MOS) having high reliability and noise immunity, and extremely low power consumption. Hence, data logging in remote areas can be accomplished easily, since a small battery pack can operate a data logger for a full year. All data retrieval modules are TTL compatible, which simplifies interfacing with external data handlers and processors such as multi-track digital recorders and digital computers.

Model DLS Data Logger / Model DRS Data Reader

The Model DLS Data Logger is an economical, compact, multiple-input, self-contained data logging recording system for field or laboratory application. It can operate on power sources of 115/230 VAC, 50/60 Hz, internal DC battery, or external storage battery. It is ideal for data monitoring over long time periods in either portable or fixed station applications. The data logger provides a permanent data record when used with air and water quality, meteorology, geophysical, process control systems and laboratory instruments. The data logger accepts up to 14 data channels (up to 99 channels are available) and records time of day, day count, and channel identification number with each set of data points. This feature is very useful in enforcement and verification applications. Perhaps the main advantage is that the data logger greatly facilitates the accumulation and processing of numerous field data. A Model ADU Auxiliary Display Unit is available for monitoring the data logger.

The Model DRS Data Reader is an economical self-contained unit designed to retrieve digital data from magnetic tape cassettes and to format the digital data for direct interfacing with data handlers and processors, such as computers, punch tape, modem, and digital printer. The instrument is fully compatible with magnetic tape cassettes recorded by any of the Series DAS Data Loggers. The information read from the tape is presented on a self-contained LED display and is simultaneously available at the output connectors. The unit will stop after reading out a number and will continue reading the next number only after receiving an internal or external "continue" command. The reader may be programmed to operate in one of the three modes: (a) reading digital magnetic tapes with an internal reading-rate control, (b) reading tapes with an external control, and (c) as a monitor and controller for any of the Series DAS Data Loggers.

Model AFP Alphanumeric Field Printer

The Model AFP Alphanumeric Field Printer was originally designed to operate with the Mark XV Water Quality Microprocessor. The Model AFP is controlled by an integral microprocessor and operates from its own rechargeable battery pack. The device utilizes a 16 character per line, dot matrix impact printer which prints approximately one line of alphanumeric data per second. The Model AFP receives data via an RS232 serial port at a data rate of 300 baud. A 2000 character buffer ensures that data over-run does not occur. The unit is normally maintained in a low-power, "idle" state where very little battery power is consumed. When data is received, the unit initiates its own power and begins printing. It will continue to print until its buffer is emptied, at which time it resumes the low power condition.

Model SDS Submersible Data Logger

The Model SDS Submersible Data Logger is a standard configuration of the Series DAS Data Acquisition and Telemetry System intended for *in situ* applications. The submersible logger may be packaged in a high-pressure housing designed to operate to water depths of approximately 650 meters, and equipped with waterproof connectors for carrying analog signals and power into the unit, as well as electrical lines to monitor and control the function of the Model SDS.

The number of active channels (up to 15 plus time of day) is selectable by a "last channel" control. By simply setting the PC board switches, the Model SDS will operate in one of three modes: (1) continuous operation, (2) On-Off mode, and (3) a single scan mode. In the ON-OFF mode, the system will turn on at a pre-selectable rate (from every 256 minutes to every 15 seconds) and will collect data for a pre-selected period of time.

Model DMP Data Microprocessor

The Model DMP Data Microprocessor features a modified Model DLS Data Logger which incorporates a microprocessor and simple keyboard control for data monitoring and system start-up that provides programmed operation for continuous data collection and analysis. The unit accepts up to 12 analog signals and will sample each data input every 30 seconds during its programmed operation. Samples are accumulated, averaged, recorded on the magnetic tape cassette, and outputted in serial format for remote data transmission. In addition to recording averaged data, the Model DMP stores and logs daily peak values and their respective times of occurrence for each data input parameter. Moreover, the Model DMP offers capability to control daily zero and calibration cycles which can provide maximum system accuracy and repeatability.

Model DRS Computer Interface

While the standard Model DRS Data Reader provides an output of parallel BCD, the DRS Computer Interface permits the Model DRS Data Reader to be interfaced with virtually any computer that accepts serial ASCII code. It is primarily designed to operate with a text-editing program. It can accept control characters for starting and stopping data transmission. A standard terminal is used to address the computer and print out echo data. It features selectable baud rates to 1200 baud with true 1200 baud throughput. It has RS232C and 20 ma loop input and output capability and permits local control of the data reader.

WELL WIZARD™ ...simplifies and speeds groundwater sampling.

Groundwater monitoring, can be costly and ineffective without the proper sampling techniques and equipment.

The WELL WIZARD™ SYSTEM has been designed and engineered to provide fast, simple, cost-effective, contamination-free sampling for the duration of your monitoring program.

The WELL WIZARD™ SYSTEM consists of dedicated downwell pumps, well-cap assemblies and a portable controller easily managed by a labor-saving single man crew. Permanent installation of the system prevents introduction of contaminants to the well...virtually eliminating any need for costly resampling or reanalyzing.

The use of a bladder pump and pneumatic controls prevents damage by solids or dry pumping. This combination, proven superior through years of independent testing, makes WELL WIZARD™ the choice of industry leaders.

Reduce your sampling costs, improve your sample integrity and protect your investment with WELL WIZARD™. Equipment engineered with experience and supported with superior customer service.

1. [illegible]

4. [illegible] achieved

2. Lockable cap protects dedicated equipment

3. One simple quick connect and system is ready [illegible]

5. Flow controls allow precise sampling rate

6. Sampling complete on to next well

3708

WELL WIZARD : a complete system approach

A FLEXIBLE SYSTEM FOR YOUR SPECIFIC NEEDS

The WELL WIZARD™ SYSTEM represents a cost effective investment in a complete system designed to meet your groundwater monitoring needs. Exhaustive engineering and extensive field experience have helped produce a complete product offering sample reliability, ease of operation and years of maintenance-free service.

The use of dedicated components simplifies sampling by eliminating on-site assembly and set-up...protecting the sample from surface contamination.

The WELL WIZARD™ portable power and control systems are designed to meet a wide range of monitoring needs. You can choose from 3 different controller options, as well as a portable or dedicated liquid level indicator, depending on your requirements.

Whatever your monitoring demands dictate, WELL WIZARD™ saves you time and money by offering reliable standardized sampling through a flexible complete systems approach.

A. PUMP
B. PURGE-MIZER
C. WELL CAP HOUSING showing quick-connect fittings
D. DRIVER-CONTROLLER
E. LIQUID LEVEL INDICATOR

WELL WIZARD ™: a clean winner

◄ **WELL WIZARD™ KEEPS ALL WATER-CONTACTING COMPONENTS FREE FROM CONTAMINATION.**

Dedication of sampling components saves time and money in setting-up, purging, sampling, cleaning and between-well transportation. Dedication of all water contacting components also helps encourage standardization of sampling techniques and controls contamination.

Other sampling ► techniques require moving pumps, tubing and cables from well to well. Costly and unreliable cleaning must be performed between sampling... dramatically increasing the potential for contamination...of the sample and the well!

WELL WIZARD : personal guaranteed service

CUSTOMER SERVICE

At Q.E.D. we believe that service is the key to continued success. That's why we've developed technical assistance and service programs that assure your personal satisfaction. Our convenient "800" number guarantees you immediate attention from our fully qualified staff.

RAPID SERVICE AND DELIVERY

Responsiveness is the key word in our service and parts department. Our professional staff is always ready to receive your calls and promptly provide parts and assistance to keep your monitoring efforts running smoothly and efficiently.

"LIFETIME" WARRANTY

We are so confident our WELL WIZARD™ system will provide trouble free service for the life of your monitoring program, we will extend a lifetime warranty for WELL WIZARD™ system components. Please contact us for details on this unique protection policy.

WELL DEDICATED COMPONENTS

PUMP, TUBING AND CAP

WELL WIZARD™ MONITORING SYSTEMS control contamination, cost and sampling method by dedicating all water contacting components to each well. The pump, tubing and cap assemblies include all water-contacting components needed for individual wells. The pumps are a bladder type design and come in a variety of materials to meet specific monitoring requirements. The well-caps include quick-connect fittings and a lockable top. Lifts of up to 300 ft. are standard; lifts of up to 1000 ft. can be accomodated with modifications. Pumps fit wells 2" and greater.

PURGE-MIZER

Reduces Purge Volumes

Purge-Mizer is an expandable collar which effectively isolates standing water above the pump. This reduces purge volume requirements significantly. The Purge-Mizer is expanded prior to purging with the same compressed air source used to drive the pump.

NON-DEDICATED COMPONENTS

MODEL 3013 CONTROLLER

The model 3013 Controller is used to cycle the pump for purging and sampling with compressed air from an external compressor or air tank. The model 3013 is used primarily where an owner has a compressed air source readily available.

MODEL 3011 DRIVER-CONTROLLER

The model 3011 Driver-Controller combines the compressed air source with the pump controller in one lightweight portable unit. The compressor is powered by an external 12V DC 8.3 amp power source. This unit is designed for use where vehicular 12V power is available and when used with a battery pack provides for ultimate portability.

MODEL 3111 DRIVER-CONTROLLER

The model 3111 Driver-Controller combines a self-contained gasoline driven compressor with the controller into a portable unit. The 3111 is used for maximum pumping rates where no vehicle access to the well or rugged terrain and travel distance between wells require high portability. The large capacity compressor allows pumping of deep wells or up to three wells simultaneously.

MODEL 6010 LIQUID LEVEL INDICATOR

The model 6010 pneumatic water level system determines the static water level without introducing "outside" elements into the well. The system employs a dedicated probe and a lightweight portable air supply.

Please consult factory regarding additional information on the components and your specific requirements.

WELL WIZARD™
Dedicated Monitoring System

PRICE LIST

CONTROLLERS AND DRIVERS

Model No.	Description	Price (1984)
3011	Controller/Driver Case mounted, automatic fully adjustable pneumatic operation. Includes integral 12 V 60 psi oilless compressor.	$2,100.00
3111	Controller/Driver Controller module (Model 3013) with 100 psi gasoline-driven compressor with versatile mobile field transporter.	$2,890.00
3013	Controller Automatic, case mounted with adjustments for flow rate and well depth.	$1,695.00

NOTE: All of the above include self coiling quick connect lines.

Prices subject to change without notice.

WELL WIZARD™
Dedicated Monitoring System

DESCRIPTION OF OPERATION

The Well Wizard is the only complete dedicated system for well monitoring. Permanent installation of the sampling device is the key to controlling the introduction of contamination to the well.

The Well Wizard system consists of dedicated downwell pumps, well cap assemblies and one portable controller.

The Well Wizard employs the use of a bladder pump. Water enters the bladder via a bottom check valve. When the bladder is full, compressed air is delivered, via an air line, to the space between the body of the pump and the bladder, which squeezes the bladder. This action closes the bottom check valve and forces the water contained inside the bladder through the upper check valve and into the attached water discharge tubing. There is no air-water contact. After the bladder is fully evacuated, the pressure inside the pump is released back through the air line to the surface. This action causes the upper check valve to close and the bottom check valve to open, refilling the bladder. Continuous operation of this pump relies upon alternating the compression/release cycle.

The small number of moving parts, the ability of this design to handle solids (including sand) without damage and the ability to withstand dry pumping make it very reliable and practical for permanent installation.

Additional advantages of this pumping method are the elimination of air/water contact, no loss of volatile organics due to air stripping and no change in sample temperature as sometimes experienced with electric pumps.

The pump is offered in two models. One is constructed entirely of rigid PVC. The other model is constructed entirely of teflon.* The bladders are also available in flexible PVC or teflon.*

Q.E.D. environmental systems inc. 1254 N. Main Street • P.O. Box 7209
Ann Arbor, MI 48107 • (313) 995-2547

The pumping device is suspended inside the well by the lines that conduct the water and compressed air. These lines are available in polypropylene, polyethylene or teflon.*

The air and water lines terminate at the top of the well casing in a snugly fitting cap assembly. The cap has a lockable top to prevent tampering. Inside the cap assembly is a panel with a fitting for the water discharge tubing and a quick connect air fitting for the compressed air supply.

The compression/release cycling of compressed air that is required to drive the pumping device is managed at the surface by a portable cycle controller. The cycle controller has several features that add to the versatility of the system.

The controller is light and compact. Its design permits the use of virtually any compressed air source. A full range of compressors, both 12 VDC and gasoline-operated, is available or the system can be driven with compressed air cylinders.

In keeping with the general dedicated approach, a dedicated static water level indicator can be included with the system. The probe portion of the static water level indicator remains in the well with the pump and is actuated through a fitting in the cap assembly.

QED's objective continues to be to provide a high quality, low cost approach to groundwater sampling equipment and techniques. We believe that the Well Wizard meets this objective by eliminating several potential sources of sample contamination, adhering to very strict material standards, providing an efficient and simple design and by reducing the time and effort required for the collection of high integrity groundwater samples.

Groundwater Sampling

WELL WIZARD™

WELL-DEDICATED COMPONENTS

Well-Wizard™ Monitoring Systems control contamination, cost and sampling method by dedicating all water contacting components to each well.

The Pump, Tubing and Well-Cap Assemblies include all water-contacting components needed for individual wells: a down-well pump, connecting tubing, a locking well-cap assembly with sample tube, and quick-connect fittings for the air supply line. The pump is designed to prevent air-water contact and avoid sample contamination. Its rugged construction allows it to pump most solids, and to lift samples from 1000 feet with minor modifications. Dedicated water-level sensing components are optionally available.

Pump Models:	Materials			Max Lift:	Flow Rate:	Dimensions:
	Body	Assembly	Bladder			
P-1100	PVC	PVC	PVC	300 ft. (std.)	0.6 GPM at 75 ft. lift	1.66 inch diam.
P-1101	PVC	PVC	TEFLON	300 ft. (std.)	with 100 PSI	36 inch length
T-1100	TEFLON	TEFLON	TEFLON	300 ft. (std.)	drive air	36 inch length
P-1200	SS	PVC	TEFLON	300 ft. (std.)	0.75 GPM at 75 ft. lift	1.5 inch diam.
T-1200	SS	TEFLON	TEFLON	300 ft. (std.)	with 100 PSI drive air	37.2 inch length

Tubing available in Polyethylene or Teflon

Well Cap Assembly PVC body with lockable protective cover. Non-locking (unprotected) also available. Contains quick-connect fitting for drive air and sample delivery tube. Available with provisions for water level sensing. Standard Assemblies fit on 2-inch or 4-inch pipe; other pipe sizes also available.

Groundwater Sampling

WELL WIZARD™

PURGE MIZER

Purge Mizer™ is an expandable collar which, when pressurized, isolates the sampling pump from stagnant water in the well. This technique substantially reduces the volume of water which must be purged prior to sampling—reducing field time and labor.

The Purge Mizer is located immediately above the Well Wizard™ pump and well screen area and is permanently dedicated to the well along with the other water contacting components of the sampling system. Air and sample lines to the sample pump pass through Purge Mizer uninterrupted and compression fittings position Purge Mizer in the well. Just prior to purging and sampling, the Purge Mizer is inflated through a fitting located in the well cap assembly. Air pressure is obtained from the portable pneumatic controller which is used to drive the pump. After sampling has been completed, the pressure in the Purge Mizer is released, allowing the device to deflate.

ıe Purge Mizer saves significant time and expense in groundwater sampling.

Material Specifications:

Rigid PVC body with Viton bladder and stainless steel clamp rings.

Purge Mizer:

Model 4200 for 2" wells
Model 4400 for 4" wells

Control Kit:

Includes all fittings, lines, gauge and relief valve
Model 4000A for 2" wells
Model 4000C for 4" wells

Model 2600
Well Sampler

ISCO

3716

Model 2600 Well Sampler features high pumping rate

ISCO's Model 2600 Deep Well Sampler is specifically designed to collect water samples from small diameter test wells, yet provides pumping rates high enough that larger diameter wells may be bailed of stagnant water and sampled with a minimum of time and effort. The pump will easily fit in wells as small as 2" I.D. and will efficiently sample at depths to 150 feet. Pumping rates using 110 psig vary from 0.5 gpm at 150 feet of head to as high as 2.0 gpm at 25 feet of head. Tanks of compressed gas are used to operate the pump.

Simple design

The pump is simple in design and operation. The control box automatically meters gas to the bladder. As the gas expands the bladder, it forces water through the upper check valve. Then when the bladder has reached its maximum expansion, gas pressure is released allowing water to enter through the lower check valve and the cycle is repeated.

Alleviates contamination

Gas does not contact the sample, eliminating the major objection to other types of gas-operated pumps. Samples contact only Delrin[1], medical-grade silicone rubber, polyethylene, and series 300 stainless steel.

Simple to use

Connecting the gas and liquid sample lines to the pump takes less than a minute. The pump is then lowered into the well to the desired depth by the polyethylene rope attached to the sample line. Connecting the gas supply and pump gas lines to the control box and setting the controls then readies the pump for operation once air is supplied.

Easy to control

Setting the sample line length switch controls bladder deflation rate, while the "sample volume" adjusts to compensate for the bladder inflation rate at varying lifts and gas supply pressure (120 psi maximum). A flow sensor in the controller monitors both direction and velocity of gas into and out of the bladder for maximum pumping efficiency.

Effective water displacement

Rapid inflation and deflation of the pump's silicone rubber bladder displaces water through check valves.

Rolling up lines

A lightweight spool is provided for convenience in rolling up lines and transporting them from site to site.

Pump efficiency*

sample line length (feet)	well head (feet)	gas pressure (psig)	gas consumption (scfm)	flow rate (gpm)
25	25	50	1.8	1.90
50	50	50	3.0	1.25
100	100	80	3.3	.90
150	150	110	3.5	.50

The table shows the most efficient pumping rates per gas consumption. Higher rates are achieved at higher gas pressure and consumption.

Specifications

PUMP:	
Physical Size:	Diameter: 1.75 in. (44.5 mm) Length: 48 in. (1219 mm)
Dry Weight:	7 lbs. 15 oz. (3.95 kg)
CONTROL BOX:	
Physical Size:	Length: 11.5 in. (292 mm) Width: 9 in. (229 mm) Height: 7 in. (178 mm)
Weight:	12 lbs. (5.44 kg)
Battery Capacity:	7 hours continuous use (rechargeable Nicad)
MAXIMUM GAS SUPPLY PRESSURE:	120 psig
MINIMUM GAS SUPPLY PRESSURE:	50 psig
MAXIMUM PUMP HEAD:	150 ft.

Optional

Sample containers with caps can be ordered in ½, 2½, 3, and 5 gallon polyethylene bottles and ½ and 2½ gallon glass bottles.

Ordering information

For a complete Model 2600 Well Sampler, you must specify the Pump, the Control Box, a Nicad battery charger, and the length of gas and sample line tubing you need (the gas and sample line tubing assembly includes the spool).

Model 2600 Pump	60-2604-001
Model 2600 Control Box with Nicad battery	60-2604-005
50' gas and sample line tubing assembly (includes reel)	60-2604-025
100' gas and sample line tubing assembly (includes reel)	60-2604-026
150' gas and sample line tubing assembly (includes reel)	60-2604-027
Control Box Battery Charger (117v)	60-2604-015
½ gallon polyethylene bottle with cap	68-2600-002
½ gallon glass bottle with cap	68-2600-003
2½ gallon polyethylene sample container with cap	299-0013-04
2½ gallon glass sample container with cap	291-0000-00
3 gallon polyethylene sample container with cap	299-0013-02
5 gallon polyethylene sample container with cap	299-0013-01
Gas line connector ferrule set	209-0171-05
Sample line connector ferrule set	209-0171-06
Extra silicone bladder tubing, 36-inch length	60-2603-032

BROCHURE 60-2603-031 February 1984 3718

MODEL 2600 PRODUCT UPDATE

Dedicated pumps

To eliminate the need to clean the Model 2600 pump and the chance of cross-contamination, a pump and tubing assembly may be dedicated to each of a series of wells, and each well sampled using a single portable control unit. Lockable well caps are available to provide security for dedicated installations. In addition, quick-disconnect fittings for the gas line hose makes set-up fast and easy.

New cable

The sample line assemblies described in the brochure have been modified to improve their utility. The braided polyethylene support rope in the sample line assembly has been replaced by a polyethylene covered stainless steel cable. The cable provides increased strength and is much easier to clean (for portable use) than the rope previously supplied. The cable is connected to the pump using the stainless steel "U" clamp supplied.

The part numbers of the sample line assemblies with stainless steel cable, cable clamp, and storage reel are as follows:

50′ sample line assembly	60-2604-025
100′ sample line assembly	60-2604-026
150′ sample line assembly	60-2604-027

ORDERING INFORMATION FOR NEW ITEMS

Well caps

Lockable well cap for 1.5″ plastic well casing (includes pump support, fittings for gas and sample lines, and 18″ delivery tubing)	60-2604-039	$50.00
Lockable well cap for 2″ plastic well casing (includes pump support, fittings for gas and sample lines, and 18″ delivery tubing)	60-2604-036	45.00
Lockable well cap for 3″ plastic well casing (includes pump support, fittings for gas and sample lines, and 18″ delivery tubing)	60-2604-033	50.00
Lockable well cap for 4″ plastic well casing (includes pump support, fittings for gas and sample lines, and 18″ delivery tubing)	60-2604-030	60.00

Quick disconnects

Connector package — control unit to gas supply (12′ coiled hose with quick disconnect fitting to control unit and male ¼″ standard pipe thread to gas supply)	60-2604-040	50.00
Connector package — gas line, control unit to well cap (12′ coiled hose with coupler to control unit and quick disconnect fitting to well cap connector)	60-2604-041	50.00
Connector package for portable use — gas line, control unit to pump (12′ coiled hose with quick disconnect fitting to control unit and male, ¼″ standard pipe thread to pump)	60-2604-042	50.00

geotech

The Geotech Small Diameter Well Pump was designed and developed in conjunction with the United States Geological Survey, Quality of Water Branch. Its purpose is to fill the requirement for a device to remove a sample from a 2" diameter well, which is less costly to drill and maintain.

This unit is ideal for ground water sampling. Because the unit is constructed of Teflon* and stainless steel, it will not contaminate your sample in any way. It can operate entirely on inert gas. It is fully automatic, portable, and can be safely operated in an explosive gas atmosphere.

This compact unit, measuring 1-3/4" in diameter and 38" in length, is operated at the well head by either our Electronic Logic Unit, or the Pneumatic Logic Unit. Both units are fully automatic, and require compressed air, nitrogen, or an air compressor. The Electronic Logic Unit also requires an AC or DC power supply. It is variable from .3 to 30 seconds on both the charge and exhaust cycles. The Pneumatic Logic Unit requires no electricity. It is variable from 0 to 60 seconds on both cycles.

A bellows of Teflon protects the sample from contamination by the inert gas power supply and is encased in a stainless steel chamber providing durability and corrosion resistance.

Twin line Neoprene hose carries the power supply to charge and bleed the chamber from one line and exhausts the sample from the other.

The inert power supply can be in the form of compressed nitrogen, compressed air or an air compressor capable of providing one-half pound of pressure for each foot of well pump depth.

The following is a description of the well pump construction and product data.

#0500 WELL PUMP

Length	38"
Width	1-3/4"
Outer Casing	Stainless Steel
Center Shaft	Stainless Steel
Bottom Check Valve	Stainless Steel
Bottom Check Valve Ball	Teflon
Plastic Strainer Disks	Polycarbonate
Bellows	Teflon
Volume of Bellows	3/4 Liter
Fittings	Stainless Steel, Quick Disconnect with Safety Washers

#5503 & #5513 NEOPRENE HOSE

Twin Line charge/exhaust Neoprene hose with quick disconnect, stainless steel fittings with safety washers.

Standard Length	100 Foot Sections
Inside Diameter per each Hose	3/8"
Outside Diameter per each Hose	1/2"
Maximum Pounds per Square Inch	200
Air Hose Color	Red
Sample Hose Color	Green

#5505 ELECTRONIC PNEUMATIC LOGIC UNIT

This unit is recommended because of the ease of operation. Charge and exhaust cycles are electronically timed and very little adjustment is needed. The unit comes with AC and DC power cords.

Minimum Pounds per Square Inch	55
Maximum Pounds per Square Inch	200
Battery Amp Draw	0.694
Electronic Timers	0.3 to 30 second charge 0.3 to 30 second exhaust
Electric Power Source	115 VAC or 12 VDC
Pneumatic Power Source	Compressed Air or Nitrogen or an Air Compressor

#5504 PNEUMATIC LOGIC UNIT

This unit is recommended if an AC or DC power source is not available or if you are working in an explosive gas atmosphere. This unit is not recommended below a 300 foot depth.

Minimum Pounds per Square Inch	70
Maximum Pounds per Square Inch	200
Controls	Pneumatic Needle Valves
Pneumatic Power Source	Compressed Air or Nitrogen or an Air Compressor

#5501 TANK REGULATOR

This unit is used with a compressed air or nitrogen tank. It consists of two gauges, a single valve 3000 PSI inlet, and a 250 PSI outlet. It also comes with a ten foot hose whip with CGA 580 quick disconnect fittings.

COMPRESSED AIR/GAS POWER SUPPLY

The Small Diameter Well Pump is designed to be operated by any inert air supply. The most common is a compressed air or nitrogen tank, or an air compressor.

For any of the above named power supplies, you can calculate the air consumption as follows. With 100 feet of hose, in or out of the well, the air consumption is 125 cubic inches per cycle, with five cycles per minute. For each additional 100 feet, add 59 cubic inches. If you plan to use an air compressor we advise that you have one with a reserve tank to insure proper air supply to the pump.

In order for the well pump to operate efficiently, you must supply adequate pressure. For each foot of pump depth, the pump utilizes 1/2 psi. An additional 10 psi is needed to assure a satisfactory flow rate. With the Pneumatic Logic Unit a minimum of 70 psi is required, the Electrical Pneumatic Logic Unit requires only 55 psi.

#5504 PNEUMATIC LOGIC UNIT

Example #1

	Pressure to Operate
100 Foot Pump Depth	
1/2 psi per foot	50 psi
For operation & line loss	10 psi
	60 psi

Adjust regulator to the required minimum of 70 psi.

Example #2

	Pressure to Operate
150 Foot Pump Depth	
1/2 psi per foot	75 psi
For operation & line loss	10 psi
Adjust Regulator to	85 psi

#5505 ELECTRICAL PNEUMATIC LOGIC UNIT

Example #1

50 Foot Pump Depth	Pressure to Operate
1/2 psi per foot	25 psi
For operation & line loss	10 psi
	35 psi

Adjust regulator to the required minimum of 55 psi.

Example #2

100 Foot Pump Depth	Pressure to Operate
1/2 psi per foot	50 psi
For operation & line loss	10 psi
Adjust Regulator to	60 psi

ADDITIONAL NOTES

There is no set minimum water depth, the only requirement is that the pump be entirely submersed at all times.

For the Electronic Logic Unit, the maximum pumping depth is 400 feet, with the pneumatic logic unit it is 300 feet.

The water contained in 100 feet of 1/4 inch I.D. hose is 59 cubic inches or 0.26 gallons. There are 231 cubic inches in one gallon.

There are 46 cubic inches contained in the bladder of the 1-3/4 inch Well Pump.

The total amount of air used per cycle is 125 cubic inches. We came to this figure by adding the amount of air in the pump, 66 cubic inches, and the amount contained in 100 feet of hose, 59 cubic inches.

* Teflon is a registered trademark of E.I. duPont de Nemours, Inc.

DESCRIPTION OF OPERATION

Water enters through the strainer (H) and passes the check valve (G), filling the Teflon bellows (D) by way of the center shaft (E). When the bellows is full, air is compressed into the chamber (C) through the top air port (A_2). This pressure closes the check valve (G) and constricts the bellows (D), forcing the water back through the center shaft (E) and past the check valve (B) to the sample port (A_1) and up the sample tubing. When the pressure is bled from the chamber (C) back through the air port (A_2), the head pressure closes the check valve (B) and the cycle is repeated.

DESCRIPTION OF WELL PUMP PARTS

(A) Quick disconnect fittings.*
(B) Top cap and check valve.*
(C) Pressure chamber.*
(D) Teflon rubber sample bellows.
(E) Center shaft.*
(F) Bottom cap.*
(G) Bottom check valve and draw-nut.*
(H) Perforated strainer.

MARTEK MARK X WATER QUALITY MONITOR

MARTEK INSTRUMENTS, INC. MANUFACTURERS OF ENVIRONMENTAL INSTRUMENTATION

. . . for field and laboratory accurate measurements of temperature, pH, conducitvity, and temperature corrected conductivity, or salinity in fresh or sea water bodies.

DESIGN AND PERFORMANCE FEATURES

- Direct in-situ measurements of temperature, pH, conductivity and temperature corrected conductivity or salinity.
- Digital panel meter display in engineering units for each parameter.
- Extended DC operation with internal, rechargeable battery pack.
- Designed for rugged field applications with simple operating controls.

DESCRIPTION

The Martek Mark X is an in-situ self-contained system for measuring temperature, pH, conductivity, and temperature corrected conductivity or salinity in the field or in the laboratory. The standard configuration, including the readout module, sensors, and 10 meters of cable which is stored within the readout module, weighs less than 6 pounds (2.7 kg); thus facilitating field monitoring under rugged environmental conditions. It can operate throughout the standard conductivity range of fresh to sea water samples without altering the conductivity sensor.

The Martek Mark X is simple to operate and provides quick, reliable and accurate data. Water quality measurements are performed by placing the multi-parameter sensor configuration in the water body or sample to be measured. A display selector switch is set to the desired parameter of measurement, which is presented on a four digit liquid crystal display. Selector switch positions are provided for reading of internal battery voltage, temperature, pH, conductivity, and temperature corrected conductivity or salinity. A conductivity "Range Selection" switch is provided on the front panel, which permits full scale conductivity sensitivities of 0-1, 0-10, or 0-100 millimhos/cm. Switching from one conductivity range to another will greatly enhance the system capability when operating in unknown water bodies, yet it will not affect the sensor calibration. Calibration controls are located under a convenient front panel access cover. Individual "Zero" and "Span" adjustments enable simple, two-point calibration of each sensor that maintains optimum system accuracy and data integrity.

The Martek Mark X system is furnished with: a readout module that incorporates a four digit liquid crystal display, a battery power supply, switch controls, front panel access to calibration controls, and a storage compartment for the 10 meter cable length and probes; battery charger, 10 meter cable length and temperature, pH, and conductivity probes; and a sturdy wooden storage and carrying case. The readout module is powered by two internal 6 volt, 0.9 amp-hour gel cell batteries. An average system current drain of less than 25 milliamps provides approximately 35 hours of continuous operation before battery charging is required. An encapsulated battery charger supplied with the system provides over-night recharge capabilities or continuous AC operation for laboratory or industrial applications. Due to its small size, light weight, simple operation and long term stability under harsh ambient monitoring conditions, the Martek Mark X is a valuable instrument for scientists, technicians, or engineers engaged in water analysis.

MARTEK MARK X SPECIFICATIONS

MEASUREMENT PARAMETERS	RANGE	ACCURACY	SENSOR TYPE

MARTEK® MARK XIV

MARTEK INSTRUMENTS, INC. MANUFACTURERS OF ENVIRONMENTAL INSTRUMENTATION

. . . in situ measurements of temperature, pH, dissolved oxygen, conductivity, and temperature corrected conductivity, or salinity in fresh or sea water bodies

DESIGN AND PERFORMANCE FEATURES

- Sensor configuration will fit two inch borehole.
- Direct in situ measurements of multiple water quality parameters.
- Digital display in engineering units for each parameter.
- AC/DC operation with internal, rechargeable battery pack.
- Designed for rugged field application with simple operating controls.
- Five element conductivity sensor operates from fresh to sea water ranges without need for changing cell constant.
- Recorder output signal for each parameter.

DESCRIPTION

The Martek Mark XIV Borehole Water Quality Monitor measurements are performed by placing the multi-parameter sensor configuration in the water body or sample to be measured. A display selector switch is set to the desired parameter of measurement, which is presented on a four digit liquid crystal display. Selector switch positions are provided for reading of the internal battery voltage, temperature, pH, dissolved oxygen, conductivity, and temperature corrected conductivity or salinity. A conductivity "Range Selection" switch is provided on the front panel, which permits full scale conductivity ranges of 0-1, 0-10, or 0-100 millimhos/cm. Switching from one conductivity range to another will greatly enhance the system capability when operating in unknown water bodies, yet it will not affect the sensor calibration. Calibration controls are located under a convenient front panel access cover. Individual "Zero" and "Span" adjustments enable simple, two-point calibration of each sensor that maintains optimum system accuracy and data integrity.

The Martek Mark XIV system is furnished with a readout module that incorporates a four digit liquid crystal display, a battery power supply, switch controls, front panel access to calibration controls, battery charger, 30 meter cable length, and a probe configuration consisting of temperature, conductivity, pH, dissolved oxygen probes and stirrer. The readout module is powered by an internal 12 volt, 1.9 amp-hour gel cell battery. An average system current drain of 50 milliamps provides approximately 35 hours of continuous operation before battery charging is required. An encapsulated battery charger supplied with the system provides overnight recharge capabilities or continuous AC operation for laboratory or industrial applications. Due to its small size, light weight, simple operation and long term stability under harsh ambient monitoring conditions, the Martek Mark XIV is a valuable instrument for scientists, technicians, or engineers engaged in water analysis.

APPLICATIONS

The Martek Mark XIV is ideally suited for in-situ water quality monitoring of ground water. The entire down hole sensor configuration is narrow to fit most two inch boreholes. In-situ monitoring avoids the problems associated with aeration, degassing, and other disturbances when samples are brought to the surface. Temperature and/or conductivity measured in boreholes may indicate the source of water at various depths or to define plumes which are usually warmer or more conductive than native ground water. Dissolved oxygen readings may be indicative of microbiological and bacterial reactions which occur in ground water. Simultaneous in-situ measurements of several parameters produces minimum disturbance of the fluid column and enhances monitoring of abrupt and irregular changes of ground water characteristics which often occurs during short intervals. The Martek Mark XIV may also be used for providing portable spot-tests, vertical profiles through water columns; bioassays; long term measurement of water samples aboard floating laboratories; in water treatment and waste water facilities; and for in-situ measurements of water bodies such as rivers, reservoirs, ponds, lakes, coastal and inland waters, and sewage and industrial plant effluents. Its unique circuitry permits digital operation under remote rugged field environments where AC power may not be available.

MARTEK MARK XIV SPECIFICATIONS

MEASUREMENT PARAMETERS	RANGE	ACCURACY	SENSOR TYPE
pH	0-14 pH	±0.1 pH	Combination pH electrode with internal silver-silver chloride reference electrode.

ORDERING INFORMATION

Part Number	
174	Martek Mark XIV Borehole In-Situ Water Quality Monitor, includes readout module, sensor configuration with temperature, pH, conductivity, dissolved oxygen probes and stirrer, 30 meter cable length, and AC battery charger. NOTE: SPECIFY 120 VOLTS OR 240 VOLTS, 50/60 HZ AC FOR BATTERY CHARGER.

All prices FOB Irvine, California including 12 month product warranty against defects in material and workmanship. Prices and specifications subject to change without notice.

MARTEK INSTRUMENTS INC.

MARTEK MARK XIV BOREHOLE WATER QUALITY MONITOR

PRICE LIST NO. 12A

PART NUMBER	DESCRIPTION	UNIT PRICE
174	Martek Mark XIV Borehole In Situ Water Quality Monitor, includes readout module, sensor configuration with temperature, pH, conductivity, dissolved oxygen probes and stirrer, 30 meter cable length, and AC battery charger.	$4,000.00
174-10	Martek Mark XIV Borehole In Situ Water Qualtiy Monitor Readout Module with AC battery charger only.	$2,000.00
174-20	Martek Mark XIV Borehole complete Sensor Configuration with temperature, pH, conductivity, dissolved oxygen probes and stirrer, and 30 meters cable length.	$2,500.00
174-21	Mark XIV Temperature Sensor	$ 210.00
174-22	Mark XIV Dissolved Oxygen Sensor	$ 490.00
174-23	Mark XIV Dissolved Oxygen Stirrer	$ 350.00
174-24	Mark XIV Conductivity Sensor	$ 280.00
174-25	Mark XIV pH Sensor	$ 210.00

NOTE: (1) Specify AC adapter for 120 volts or 240 volts, 50/60 Hz.

(2) All prices FOB, Irvine, California. Prices and specifications subject to change without notice. Delivery 30 days after receipt of order.

ISCO

wastewater samplers

3731

high speed samplers

ISCO wastewater samplers are designed to collect individual or composite water samples taken from streams, manholes, or other sources at precisely timed or flow-proportioned intervals. Completely weatherproof, corrosion resistant construction and the ability to handle relatively large suspended materials suit them for use in industrial, food processing and meat packing plants, paper mills, and municipal sewage treatment plants or along rivers, sewers and tidelands.

Circular construction permits easy lowering into any standard manhole without dissassembly or tipping. The case is quickly snapped apart to expose all sections for servicing. Originated by ISCO, this efficient design has been field proven and copied by others. The sample compartment may be padlocked during operation to prevent tampering with collected samples.

Tripod-mounted sampler being installed into a sewer, tideland, or stream.

ISCO portable samplers can be powered by one of four sources: a removable, rechargeable Nicad or lead-acid battery located inside the sampler; an external automotive battery; or AC line. The dry Nicad battery has an extremely long recharge life, cannot spill acid, does not require refilling, and will not freeze. ISCO lead-acid batteries are of the sealed gel type and also will not spill or require refilling. A removable power converter/battery charger can be used to replace the internal batteries when AC line power is available.

The best feature of ISCO samplers — reliability — does not show up on the specification sheet. Time and again the many thousands of ISCO samplers currently in use have been shown to outlast competing samplers in adverse environments. ISCO samplers can be demonstrated in most areas by sales representatives. Contact the factory or your representative for more information on this equipment, or for formal specifications to help prepare your bid request.

reliable, versatile control

In addition to normal timed collection, all ISCO samplers offer flow proportioned collection when used with an ISCO or other flow meter. Sample interval and volume can be set over wide ranges with simple switch controls. The controller cover has an erasable log to record sampling locations, battery recharging dates, and other data as needed. Programming instructions with examples are permanently attached to the controller lid for quick training of unskilled operators. Four wing nuts allow the controller mechanism case to be removed as a unit for servicing.

Sample size is determined with a typical repeatability of ±10 ml. Other samplers utilizing the vacuum principle determine sample size by overfilling a metering chamber and siphoning away the excess, frequently resulting in solids settling from the excess into the retained sample to artificially enrich BOD and suspended solids levels. ISCO's elimination of the metering chamber avoids this problem, reduces cross-contamination between samples, and prevents reliability troubles arising from grease-fouled electrodes, vacuum leaks, plugged valves, or other failures in the complex sequencing mechanism required for the operation of metering chambers.

rugged, watertight construction

ISCO samplers can withstand thorough cleaning with a hose and even prolonged submersion. All electrical and mechanical components—not just the controller—are sealed in a single watertight stainless steel housing to provide reliable operation in manholes and similar corrosive environments. Quick locking toggle clamps and a seamless gasket provides fast, secure sealing of the controller cover*. Switches have rubber boots for protection against wet fingers, and the housing contains a regenerable desiccant cartridge to absorb moisture seepage or condensation. An indicator tells when to oven dry the desiccant to restore its original absorptive capacity. All exposed hardware is stainless steel; there are no exposed painted or plated steel parts.

This composite sampler base was cut away to determine damage after drop testing. A complete sampler with a 40 lb. load was dropped three times at heights to 9'. The only damage was separation of the insulation visible in bottom corner. Inner and outer shells were intact and the sampler was completely serviceable.

The entire case is constructed of high impact plastic, and exhibits excellent mechanical strength. The case is resistant to gasoline and similar solvents in water, but is not compatible with chlorinated hydrocarbons. All ISCO sampler bases have an inner and outer shell, separated by rigid, foamed-in-place polyurethane insulation. Durability and insulating properties are far superior to samplers using modified plastic trash containers or one piece picnic cooler type moldings. Large compartments for block or crushed ice provide proper cooling for samples scheduled for BOD or TOC analysis.

All mechanical, pneumatic and electronic components are sealed in the watertight stainless steel case. The high speed, large bore pump is a rugged and virtually maintenance free.

*Watertight if seals are intact. Each unit is individually tested for leaks before it leaves the factory. However, once the conditions of use are beyond ISCO's control, maintaining watertightness is not guaranteed.

This Model 1680 sampler functioned perfectly after being dragged seven miles down a muddy river. No water leaked into the stainless steel case containing all motors and electronic components. Even the head battery was unaffected by prolonged submersion.

high speed, clog-proof pump

Samples are taken with a high speed, large bore (3/8") peristaltic pump. There are no valves or reciprocating parts — only a flexible tube through which the sample is forced by the squeezing action of moving rollers. This simple, clog-proof pump is extremely dependable and requires minimal maintenance. The peristaltic tubing is a separate length of silicone rubber, providing better performance and longer life than obtainable in pumps where the rollers run on a portion of the vinyl suction line. The silicon rubber pump and distribution tubing used in ISCO samplers is a special medical grade tubing which contains absolutely no organic material that will contaminate the sample or destroy its integrity.

Both before and after sampling, the pump reverses to air purge the suction line and minimize cross-contamination between samples. Suction lines have streamlined, weighted strainers to keep rags and other debris from entering the sampler. Suction lines of vinyl or Teflon®, 1/4" or 1/2" I.D., are available for general purpose or toxic pollutants sampling applications.

Intake velocity is close to optimum — fast enough to prevent settling of suspended solids, but not fast enough to pick up static bottom sediments which may provide an inaccurately high BOD value*. Although the EPA has no requirements regarding suction line velocity, its report EPA-R2-73-261 states (p. 221): "minimum velocity of two to three feet per second would appear warranted". The standard ISCO pump provides a typical line velocity of over 2'/sec with a 1/4" suction line at heads to 12'. If a higher line velocity is preferred for some unusual application, a superspeed pump operating at four times the standard rate is available. This provides a line velocity typically over 3½'/sec through a 3/8" suction line, but is not recommended for general sewage sampling as it can produce erroneously concentrated BOD and TSS samples if the strainer is too near the bottom of the stream.

The location of an ISCO sampler does not significantly affect sample composition, sometimes a real problem with vacuum operated samplers where suction line velocity, and hence sample composition, varies greatly with only a few feet difference in head height. An ISCO sampler, whether it's at the bottom or top of a manhole, always provides the same sample. Maximum head is 26'.

ISCO pumps provide adequate line velocity without unacceptable variation over varying head heights. Sample composition is more representative than with low speed peristaltic pumps and uniform vacuum taken at different head heights is superior to vacuum systems. Maximum lift is also greater than with most other samplers.

*In the last several years the EPA and other government agencies have thoroughly researched sampling methods and equipment. Their results show that suction line velocity is only one of many variables affecting sample composition, and that line velocity differences within a reasonable range (approximately 2 to 3'/sec) do not have a consistent effect on sample composition. Outside of this range, certain low velocity piston or peristaltic pumps and high velocity vacuum samplers often produce large composition deviations. EPA reports have repeatedly shown that vacuum operated samplers produce higher BOD and other composition values than grab samples.

model 1680 high speed sequential sampler

A Model 1680 sequential sampler can really simplify your pollution monitoring program. Reliable operation provides reproducible results you can trust; programming versatility insures against obsolescence due to changing regulations, and manhole-proof ruggedness withstands corrosive atmospheres, wear and tear, and frequent hosing or even total submersion. For taking a single composite sample, the standard 28 bottle sequential base section may be replaced with a base accommodating a single wide-mouth container.

Typically, over one hundred full samples may be taken on an 18 hour charge of the removable Nicad or lead acid battery. An auxiliary battery within the controller maintains the logic for about eight hours in case of a power failure. While it will not power the pump, it accommodates power interruptions and battery changes without losing the program or time.

The one piece, clog-proof rotating tunnel carries samples to the distributor plate without passing through any rotating seals or hard-to-clean tubing; the steep trough angle prevents sedimentation. Samples are conducted into individual bottles by a distributor plate. Both the tunnel and distributor plate can be quickly removed for cleaning.

The base holds 28 bottles — four more than usual, to take the pressure off 24 hour servicing schedules. A large ice compartment is provided for cooling biological specimens. Its capacity is adequate to maintain samples at about 40°F below ambient for at least 12 hours, and 30°F below ambient for 24 hours. Construction is double-walled high impact plastic with foamed-in-place insulation having a nominal thickness of 1". Additional bases with covers and bottles may be obtained to retrieve samples from the field without interrupting collection. The cylindrical sample bottles are available in unbreakable, high density polyethylene (500 ml) or glass (400 ml). They are much easier to clean than wedge-shaped bottles since they have a wide mouth to admit a large brush and have no inaccessible corners. Polyethylene bottles can be washed in a dishwasher but not autoclaved. Glass bottles can be autoclaved and are also suitable for samples having organic components which may be absorbed by plastic bottles. All bottles are supplied with caps with polypropylene liners to insure safe handling. Teflon® lid liners are available separately for all ISCO bottles.

Outside dimensions are 21" high by 19½" diameter and the weight is 40 lbs. with battery and polyethylene bottles.

Accessory composite base

The all-electronic controller provides collection intervals determined by the 1 to 999 minute quartz crystal timer or by any ISCO flow meter. Up to 999 signals from the flow meter can be combined for each sample. This greatly expands the range of flowstream volumes originally available in the flow meter, and simplifies interfacing with flow meters or other manufacture. Sampling normally commences immediately upon setup, but the initial sample can be delayed up to 999 minutes if desired. All values are entered with a pushbutton digital switch. An LED display shows the interval remaining before the next sample is taken.

Model 1680 controller

Maximum sample volume is 500 ml selected with a 9 position switch. The switch scale indicates volumes for head heights to 21'. Another switch provides for the selection of six different suction line lengths. An optional multiplexer permits compositing 1, 2, 3, or 4 samples into each bottle, allowing a maximum of 112 samples to be placed into the 28 bottles. This provides more representative collection and reduces the danger of missing short term changes in stream composition. The multiplexer also can be used to distribute the sample over 1, 2, 3, or 4 bottles, permitting a larger sample volume or the use of several different preservatives. An automatic shutoff stops the sampling program after the last bottle is filled. An optional switch is available to by-pass the automatic 28th bottle shutoff when using the composite base accessory. When the sampler is returned to sequential sample collection, the switch may be placed in the shut-off position to cease sample collection after the 28th bottle has been collected.

For each complete Model 1680 you MUST SPECIFY the basic unit, a power source, and a suction line with strainer

THE BASIC UNIT

Catalog Number	Pump	Bottles	Multiplexer?
68-1680-06	Standard	Polyethylene	Yes
68-1680-068	Standard	Polyethylene	No
68-1680-069	Standard	Glass	Yes
68-1680-070	Standard	Glass	No
68-1680-071	Superspeed	Polyethylene	Yes
68-1680-072	Superspeed	Polyethylene	No
68-1680-073	Superspeed	Glass	Yes
68-1680-074	Superspeed	Glass	No

POWER SOURCES

Nicad Battery without charger	60-1684-080
Lead Acid Battery with clamp without charger	60-1684-062
AC power converter/battery charger. To power sampler from 115VAC 50/60 Hz line power or to recharge battery for use with standard speed pump samplers only	60-1684-046
Same as above except for use with superspeed pump samplers	60-1684-088
Same as above except for 230VAC 50/60 Hz line power and for use with standard and superspeed pump samplers	60-1684-071

SUCTION LINES

3/4" ID x 22' vinyl suction line with polypropylene braided inlet strainer. For use with standard speed pump samplers only	60-1194-054
3/8" ID x 20' vinyl suction line with polypropylene braided inlet strainer. For use with standard and superspeed pump samplers	60-1684-035

ACCESSORIES

Extra base with 28 polyethylene 500 ml bottles. Without cover	60-1194-069
Same except 28 glass 400 ml bottles. Without cover	60-1684-100
Cover for 28 bottle base	60-1194-067
Sample bottles, high density polyethylene, 400 ml with caps with polypropylene lid liners. For Models 1680, 1392 and late Model 1392. With caps removed will also fit Model 1580 or earlier Model 1392 with X or W in serial number. Set of 28	68-1680-029
Same. Case of 100. Without caps	68-1680-030
Caps for PE sample bottles. Case of 100	68-1680-031
Sample bottles, glass, 400 ml with caps with polypropylene lid liners. For use in 1580, 1581, 1582, 1680 for 1680 Samplers. Set of 28	68-1680-032
Teflon lid liners for 400 ml glass bottle, per each	60-1681-117
Composite base only. Does not include bottle container or locking insert. Sold separately below	60-1684-081
4 Gallon polyethylene container with lid and polypropylene lid liner. Requires locking insert below	299-0011-02
1 Gallon bottle, no locking insert	60-1681-020
5 Gallon polyethylene container with lid and polypropylene lid liner. No locking insert required	299-0011-01
2 ½ Gallon glass container with lid and polypropylene lid liner. Requires locking insert below	299-0000-00
2 ½ Gallon bottle, locking insert	60-1681-088
Teflon lid liner for 2 ½ Gallon bottle, each	60-1681-092
Cover for composite base, stainless only	60-1684-107
By-Pass Switch installed for composite sampling	**68-9680-064**
Extra silicon rubber pump tube, for Models 1680 and 1392, 17" long	60-1684-016
Extra silicon rubber pump tubing, bulk, 15' long	68-1680-063
Snap-on suspension harness	60-1394-014
Liquid level sampler actuator	60-1644-000
Automotive battery cable	60-1394-024

model 2100 sampler

Since the passage of the CLEAN WATER ACT of 1977, water sampling and testing has been expanded to include a class of substances known as "toxic pollutants". Because of the very low concentration limits that have been established for these substances, automatic samplers constructed of materials that do not contribute to or absorb from the sample are an absolute necessity. The ISCO Model 2100 Sampler has been designed specifically for toxic pollutant sampling and, because of this design is equally well suited for suspended solids and general purpose sampling applications. The versatility that has been built into the Model 2100 makes it possible for the user to adapt the instrument to a wide variety of applications.

The Model 2100 is a portable automatic wastewater sampler designed to collect up to 24 separate sequential samples of a pre-determined volume. The samples may be collected in your choice of 350ml glass or 1000ml polypropylene bottles. Both bottles are interchangeable in the same base. The samples can be collected on a time basis using the internal quartz crystal clock, or on a flow proportional basis using a 12VDC pulse or isolated contact closure input from an external flow meter. In the time mode, the interval between samples may be set from 1 to 999 minutes in one minute increments or, in the flow mode, the interval between samples may be set from 1 to 999 flow pulses in single pulse increments. A manual sampling cycle may be initiated at any time. Sample volumes are adjustable in 10ml increments to a maximum of 1000ml. Each sampling cycle includes an air pre-purge and post-purge to clear the suction line.

A standard feature of the Model 2100 is an eight position multiplexer allowing up to eight sample bottles to be filled at each sampling interval or up to eight samples to be placed into each sample bottle. An LED readout indicates the bottle number and the multiplex step (if multiplexer is being used) of the next sample. A second LED readout indicates the interval in minutes or flow pulses remaining until the next sample is to be collected. Both LED displays are visible through a viewing window in the sampler control box lid, allowing the progress of the sampling program to be monitored without opening the control box. The sampler also features an adjustable time delay to the first sample providing the operator with up to 999 minutes delay before the first sample is taken. After the time delay, sample collection proceeds at regular time intervals.

The Model 2100 Sampler uses the proven ISCO peristaltic pump system to transport the sample from the source to the sample bottle. The flow rate is typically 3000 milliliters per minute. The sample is under pumped flow at all times: there are no metering chambers, valves, or gravity-fed internal distribution systems. The only materials in contact with the sample are the vinyl or Teflon® suction line, the polypropylene and stainless steel inlet strainer (use optional), and the silicone rubber pump and distribution tubing. The silicon rubber pump and distribution tubing used in ISCO samplers is a special medical grade tubing which contains absolutely no organic material that will contaminate the sample or destroy its integrity. These features make the Model 2100 eminently suitable for both suspended solids and toxic materials sampling. Cross contamination between samples is minimized by eliminating sites for sediment accumulation and by limiting the materials in contact with the sample to silicone rubber, Teflon® (when a Teflon® suction tube is used) and glass. Very stringent requirements regarding the cleaning and handling of samplers for toxic materials have been established. Cleaning the Model 2100 between sampling locations is accomplished by merely replacing relatively inexpensive lengths of tubing and washing the bottles in the prescribed manner. Ambient operating temperatures range from 32°F to 120°F in weather conditions including rain and dust. Basic construction is of vacuum formed ABS plastic and stainless steel. The controls and electronics are housed in a watertight stainless steel container. The 24 bottle base and the center section which supports the control box and which forms the cover for the base are well insulated and the base will hold at least 30 pounds of crushed ice for sample cooling. Power sources can be either 117VAC, 50/60 Hz line current (234VAC, 50/60 Hz optional), or a battery of 12VDC. ISCO customers will find the Model 2100 to be of the usual high ISCO quality and of advanced design and versatility.

Standard controls

model 2100 options

COMPOSITE SAMPLING — A special insert is supplied with the Model 2100 Sampler to allow composite sampling in the 24-bottle base. The insert positions one 2½ gallon glass or polyethylene container (container must be ordered separately). For larger composite samples, a larger base assembly is available to accommodate 3 or 5 gallon containers.

SPECIAL TIMING SEQUENCES — For certain applications (for example, run-off or combined sewer overflow studies) it may be desirable to collect samples in a timed mode where the time interval between samples does not remain constant, but changes in a preprogrammed manner as the sampling program progresses. Up to four such special timing sequences may be specified to be included in the sampler electronics as an extra cost option. Normally, an ISCO Model 1640 Liquid Level Sampler Actuator would be used when operating on the special timing sequence, but is not absolutely necessary.

In operation, the sampler would remain dormant until the water rises to a predetermined level, at which time the sampling program is initiated. The special timing sequence is normally established such that a number of samples are collected at rapid intervals to monitor the initial run-off, with the sample interval gradually increasing during the remainder of the sampling period.

OPTIONAL MODES OF OPERATION — The Model 2100 has four basic built-in optional modes of operation. These modes slightly modify the normal operation of the sampler to accomplish some special purpose. These modes of operation include a composite sampling mode, short purge mode when multiplexing samples into separate bottles, four liquid level sampler actuator sample initiation modes and a sample line pre-condition mode.

The composite mode is used for collecting composite samples. In operation, "NEXT SAMPLE" LED shows the total number of individual samples which have been placed in the sample container. The total number of samples to be placed in the sample container before the sampler is automatically shut off can be set on the MULTIPLEX switch to ensure that the container does not overflow.

The short purge mode is used when collecting more than one bottle per sample using the multiplexer. It disables the pre- and post-purge function between the bottles, substituting a short purge to keep the distributor from dripping between bottles, to conserve battery power and to reduce the time between samples to maximize uniformity. The pre-purge before the first bottle and post-purge after the last bottle in the multiple bottle sample sequence are unchanged.

The sample line precondition mode provides for a prewash of the sample line to reduce the chance of cross-contamination due to residue in the suction tube and pump from the previous sample.

The liquid level sampler actuator sample initiation mode provides four different sampling sequences by which the Model 2100 Sampler collects samples when used with the Model 1640 Liquid Level Sampler Actuator. Basically, this provides a means of controlling the time which the first sample is collected in relation to the balance of the samples.

The optional modes of operation are built into the Model 2100 and are selected by internal switches. It is relatively easy to return the Model 2100 Sampler to its normal mode of operation after being used in the optional mode.

model 2100 specifications

PHYSICAL SIZE	Height: 25 in Diameter: 14 in
DRY WEIGHT	40 lb
SAMPLE BOTTLE CAPACITY	24 with Teflon® lid liners
SAMPLE VOLUME	150ml in glass bottles, 1000ml in polypropylene bottles, incremental maximum 1000ml incremental volume, composite maximum
SAMPLE VOLUME REPEATABILITY	±10ml typical
SAMPLING FREQUENCY	1 to 999 minutes between consecutive samples in 1 minute increments, or 1 to 999 flow pulses in single pulse increments
SAMPLING MODES	Timed, or flow proportional to external flow meter
FLOW METER INPUT REQUIREMENT	12VDC pulse or isolated contact closure of at least 25 milliseconds duration
SUCTION INTAKE TUBING	3/8" I.D. x 20' vinyl 1/4" I.D. x 22' vinyl 1/8" I.D. x 10' or 20' Teflon®
SUCTION LIFT	26 feet maximum
PUMP RATE (1 cu HEAD)	1/4" I.D. suction tube: 2400ml/min 1/8" I.D. suction tube: 1000ml/min
LINE TRANSPORT VELOCITY (1 cu HEAD)	1/4" I.D. suction tube: 4.1 ft/sec 1/8" I.D. suction tube: 2.1 ft/sec
TIME BASE ACCURACY	Better than 0.01% quartz crystal controlled clock
AMBIENT TEMPERATURE RANGE	32° to 120°F
CONTROL BOX WATER TIGHTNESS	Maximum leak rate — 0.1 ml/hr at 1 cu head (1 oz in place), flow meter connector capped and battery or power pack attached to 12VDC connector
COOLING CAPACITY (with 30 lbs ice in bottle section and 24 bottles full of DI water	After 24 hrs: 35°F below ambient After 48 hrs: 25°F below ambient
POWER REQUIREMENTS	Sampler: 12VDC Power Converter: 117VAC, 50/60 Hz 234VAC, 50/60 Hz (optional)
EXTERNAL NICAD BATTERY CAPACITY	150 full bottles typical after 10 hr charge
INTERNAL NICAD BATTERY CAPACITY	Maintains internal logic and timing circuits 30 hr minimum when fully charged

For each complete Model 2100 you MUST SPECIFY the basic unit, a power source, and a suction line with strainer.

THE BASIC UNIT	
Model 2100 Sampler with multiplexer and 24 — 150ml glass bottles	60-2100-005
Same except with 24 — 1000ml polypropylene bottles	60-2100-006
POWER SOURCES	
Nicad battery, without charger	60-1684-060
Lead Acid battery, with clamp, without charger	60-1684-062
AC power converter/battery charger, 117VAC, 50/60 Hz	60-1684-068
Same except 234VAC, 50/60 Hz	60-1684-061
SUCTION LINES AND STRAINERS	
1/4" I.D. x 22' vinyl suction line with weighted polypropylene hooked strainer	60-1194-014
1/8" I.D. x 20' vinyl suction line with weighted polypropylene hooked strainer	60-1684-015
1/8" I.D. x 10' Teflon® suction line, Neoprene® rubber protective coating, without strainer	60-1683-146
Same except 20' length	60-1683-144
Weighted strainer only, 3/8" all stainless steel	60-1684-110
Teflon® suction line flaring tool to allow insertion of above strainer	60-2101-093
ACCESSORIES AND OPTIONS	
Extra base with 24 — 150ml glass bottles and caps	60-2104-021
Extra base with 24 — 1000ml polypropylene bottles and caps	60-2104-016
Special Timing Sequence — Add up to four special timing sequences through the addition of a special jumper on the MODE switch. Customer must complete Model 2100 information sheet	60-2100-004
Liquid level sampler actuator	60-1644-080
2½ gallon polyethylene container with cap, for composite sampling in 24-bottle base	299-0013-04
2½ gallon glass container with cap, for composite sampling in 24-bottle base	291-0080-00
Cover for extra base (for either standard or composite base)	60-2104-061
Composite base only. Does not include container or locating insert listed separately below.	60-2104-046
3 gallon polyethylene container with cap, for use in composite base. Requires locating insert below	299-0013-02
3 gallon locating insert	60-1483-020
5 gallon polyethylene container with cap, for use in composite base. No locating insert required	299-0013-01
Sample bottles, 150ml glass with Teflon® lined caps, set of 24	60-2103-001
Sample Bottles, 1000ml polypropylene with Teflon® lined caps, set of 24	60-2103-007
Sample Bottles, 150ml glass without caps, case of 100	60-2100-002
Caps for 150ml glass with Teflon® liners, case of 100	60-2100-003
Sample Bottles, 1000ml polypropylene without caps, case of 100	60-2100-008
Caps for 1000 ml polypropylene bottles, case of 100	60-2103-010
Extra silicone rubber pump and distribution tubing (3' length)	60-2104-054
Extra silicone rubber pump and distribution tubing, bulk (3' length)	60-1680-061
Snap-on suspension harness	60-1194-014
Automotive battery cable	60-1194-023

*Dupont

model 1580 composite sampler

The Model 1580 composite sampler pumps uniform, small sample increments into a single receptacle at programmed timed or flow-proportioned intervals. Although very economical, it has all of the ISCO features described on pages 1, 2, and 3. It adapts to battery or line power, and has an insulated ice compartment and automatic shutoff. The instrument is weatherproof with a single watertight, stainless steel housing for all electronic and mechanical components. Up to 40 gallons may be taken on an 18 hour charge of the optional Nicad or lead-acid battery.

Accurately calibrated switches allow precisely sized samples to be taken without involved computation. Sampling frequency can be continuously adjusted to any time from 2½ to 320 min, while the incremental volume can be varied from 40 to 600 ml. The intake line is purged before and after each increment to ensure that the sample is representative of the time at which it was taken, and to reduce cross-contamination. The Model 1580 composite sampler is available with either the standard or superspeed pumps.

An optional ISCO flow meter enables the sampler to collect a composite based on the volume of passing fluid rather than on time. In the flow-proportioned mode, the uniform increments are taken at a frequency which is proportional to the flow rate of the stream. The Model 1580 can multiply, by a factor from 1 to 9, the volume that has been preselected on the flow meter.

The sample is under pumped flow at all times: there is no gravity-fed internal tubing. Samples are collected in a three or five gallon high density polyethylene container or a 2½ gallon glass container. The container drops into the insulated base section without attaching any tubes or spouts, and has a mouth wide enough to insert an arm and brush for vigorous cleaning. An automatic, magnetically-coupled float shutoff terminates sampling when the container is full to prevent overflow if the sampler is not serviced on schedule. The base itself can be used for samples up to 10 gallons, and the controller section can be placed on a larger drum for special applications requiring unusually large samples.

Case sections, constructed of high impact plastic, snap apart to expose the entire unit for cleaning with a hose. The removable base section is constructed with thick foamed-in-place insulation, and can be iced to initially cool and keep a three gallon sample below 55°F for over 24 hours in 100°F environment. Stainless steel hasps allow padlocking to prevent tampering with the sample.

Diameter of the sampler is 19", height is 25½", and weight is 31 lb. See page 14 for sampler accessories.

For each complete Model 1580 you MUST SPECIFY the basic unit, a power source, suction line with strainer, and sample container.

THE BASIC UNIT

Model 1580 Sampler with standard pump	60-1684-015
Same, except superspeed pump	60-1684-017

POWER SOURCES

Nicad Battery, without charger	60-1684-040
Lead-Acid Battery, with charger, without charger	60-1684-062
AC power converter/battery charger. To power sampler from 117VAC, 50/60 Hz line power or to recharge batteries, for use with standard speed pump/sampler only	60-1684-046
Same as above, except for use with superspeed pump/sampler only	60-1684-060
Same as above, except for 234VAC, 50/60 Hz line power, and for use with both standard and superspeed pump/samplers	60-1684-061

SUCTION LINES AND STRAINERS

1/4" I.D. x 22' vinyl suction line with weighted polypropylene flutted strainer	60-1394-054
1/8" I.D. x 20' vinyl suction line with weighted polypropylene fluted strainer	60-1684-015
1/8" I.D. x 10' Teflon® suction line, Neoprene® rubber protective coating, without strainer	60-1684-146
Same, except 20' length	60-1684-144
Weighted strainer only, 1/8", all stainless steel	60-1684-110
Teflon® suction line flaring base to allow installation of above strainer	60-2101-094

SAMPLE CONTAINERS

1-Gallon polyethylene container with lid and polypropylene lid liner. Requires lex sling insert below	299-0011-032
1-Gallon bottle lex sling insert	60-1681-020
3-Gallon polyethylene container with lid and polypropylene lid liner. No lex sling insert required	299-0011-031
2½ Gallon glass container with lid and polypropylene lid liner. Requires lex sling insert below	291-0000-003
2½ Gallon bottle lex sling insert	60-1681-098
Teflon lid liner for 2½ Gallon bottle cap	60-1681-097

ACCESSORIES

Extra silicone rubber pump tube, 27½" long	60-1584-015
Extra silicone rubber pump tubes, bulk, 15' long	60-1640-061
Snap-on suspension harness	60-1394-014
Liquid level sampler actuator	60-1644-000
Automotive battery cable	60-1394-023

refrigerated samplers

These three refrigerated samplers preserve biological specimens during and after collection. They are light and compact, and can be easily installed in any place affording reasonable protection from the elements. They are suitable for use whenever permanent installation is required. The controller/pump assemblies on two of these samplers are identical to, and interchangeable with, those of the Models 1680 and 1580 portable samplers. Information relating to sample collection will be found in the descriptions of these portable samplers. A refrigerated version of the Model 2100 is not available.

The Model 1580R refrigerated composite sampler can be supplied with a 3 or 5 gallon polyethylene container or a 2½ gallon glass container. These containers have a large mouth and are easily cleaned. When the container is filled to any predetermined level, a weight activated switch stops the sampling process and a red indicator light alerts the operator.

The Model 1680R uses the sequential controller and a slide-in 28 bottle rack. Ample room is provided for 32 additional loose bottles.

A third refrigerated sampler, the Model 1682R, takes eight samples of up to two liters each in either glass or polyethylene bottles. The standard controller includes a multiplexer so that eight identical composite samples may be taken with a different preservative in each bottle if desired. For other purposes, eight large sequential samples may be collected, with each sample being a composite of up to eight smaller increments. The Model 1682R has no portable equivalent. Controller specifications are basically the same as the Model 1680, but a Model 1680 controller cannot be converted to the eight bottle version.

Rigid foamed-in-place insulation stiffens the refrigerated compartment, and will not support bacterial growth or retain odors. Both the controller and sample compartment may be individually padlocked. The door utilizes a magnetic gasket for better sealing. Sample temperature can be selected from 32° to 46°F (0° to 8°C) with a calibrated control. A forced air condensing coil and front ventilation allow positioning the unit against a wall or in a corner without leaving clearance on the back or sides. Wraparound construction of the oversized evaporator coil provides quick and efficient cooling of the sample compartment. Defrosting is not required under normal operating conditions.

If it is desired to convert a presently owned portable sampler to a refrigerated unit, or to have both portable and refrigerated options on the same sampler, a refrigerator unit only may be ordered. These units are identical to the complete refrigerated samplers except the controllers (programmer and pump assemblies) are excluded. Changing a controller from the portable to the refrigerated version takes only a few minutes. Each refrigerated unit includes the sample container(s), suction line, and all standard accessories.

Height of the cabinet is 42½", width is 24¾", and depth is 25½". Net weight is 116 lb. Available for AC line power only.

A COMPLETE REFRIGERATED 1680R or 1682R SAMPLER CONSISTS OF:
1. THE BASIC UNIT
2. SUCTION LINE AND STRAINER

YOU MUST SPECIFY YOUR CHOICE OF THE ABOVE FROM 1 AND 2 BELOW:

1. THE BASIC UNIT

A. MODEL 1680R for 117VAC, 60HZ OPERATION

Catalog Number	Pump	Bottles	Multiplexer?
[illegible]	Standard	Polyethylene	Yes
[illegible]	Standard	Polyethylene	Yes
[illegible]	Standard	Glass	Yes
[illegible]	Standard	Glass	Yes
[illegible]	Super-speed	Polyethylene	Yes
[illegible]	Super-speed	Polyethylene	No
[illegible]	Super-speed	Glass	Yes
[illegible]	Super-speed	Glass	No

B. MODEL 1680R FOR 234VAC, 50HZ OPERATION

[illegible]	Standard	Polyethylene	Yes
[illegible]	Standard	Polyethylene	No
[illegible]	Standard	Glass	Yes
[illegible]	Standard	Glass	No
[illegible]	Super-speed	Polyethylene	Yes
[illegible]	Super-speed	Polyethylene	No
[illegible]	Super-speed	Glass	Yes
[illegible]	Super-speed	Glass	No

C. MODEL 1682R FOR 117VAC, 60HZ OPERATION

[illegible]	Standard	Polyethylene	Yes
[illegible]	Standard	Glass	Yes
[illegible]	Super-speed	Polyethylene	Yes
[illegible]	Super-speed	Glass	Yes

D. MODEL 1682R FOR 234VAC, 50HZ OPERATION

[illegible]	Standard	Polyethylene	Yes
[illegible]	Standard	Glass	Yes
[illegible]	Super-speed	Polyethylene	Yes
[illegible]	Super-speed	Glass	Yes

2. SUCTION LINES AND STRAINERS

1/4" (ID) x 22' vinyl suction line with polypropylene heated inlet strainer, for use with standard-speed pump samplers only	[illegible]
1/8" (ID) x 20' vinyl suction line with polypropylene heated inlet strainer, for use with standard and super-speed pump samplers	[illegible]

ACCESSORIES FOR 1680R and 1682R

Extra 28 bottle rack for Model 1680R with polyethylene bottles	[illegible]
Extra 28 bottle rack for Model 1680R with glass bottles	[illegible]
For extra bottles only for the Model 1680R, see Page 6	
Extra 8 bottle rack for Model 1682R with polyethylene bottles	[illegible]
Extra 8 bottle rack for Model 1682R with glass bottles	[illegible]
Polyethylene bottles only for Model 1682R, set of 8 with caps	[illegible]
Glass bottles only for Model 1682R, set of 8 with caps	[illegible]
Teflon lid liners for 2 liter glass bottles	[illegible]
Extra silicone rubber pump tube for either Model 1680R or 1682R 17"	[illegible]
Extra silicone rubber pump tubing, bulk, 15' long	[illegible]

Model 1680R

Model 1580R

A COMPLETE MODEL 1580R REFRIGERATED SAMPLER CONSISTS OF
1. THE BASIC UNIT
2. A SAMPLE CONTAINER
3. A SUCTION LINE WITH STRAINER

YOU MUST SPECIFY YOUR CHOICE OF THE ABOVE FROM 1, 2, AND 3 BELOW:

1. THE BASIC UNIT

Catalog Number	Pump	Power Source
[illegible]	Standard	[illegible]
[illegible]	Super-speed	[illegible]
[illegible]	Standard	[illegible]
[illegible]	Super-speed	[illegible]

2. SAMPLE CONTAINERS

3 Gallon polyethylene container with lid and polypropylene lid liner	[illegible]
5 Gallon polyethylene container with lid and polypropylene lid liner	[illegible]
2½ Gallon glass container with lid and pump-type lid liner	[illegible]
Teflon lid liner for 2½ Gallon bottle only	[illegible]

3. SUCTION LINES AND STRAINERS

1/4" (ID) x 22' vinyl suction line with optional pump-protect heated strainer	[illegible]
1/8" (ID) x 20' vinyl suction line with optional pump-protect heated strainer	[illegible]
1/8" (ID) x [illegible] Teflon® suction line, "Neoprene®" rubber pump-tube coupling, without strainer	[illegible]
Same except 20' length	[illegible]
Weighted strainer only, 1/8" (ID) x [illegible]	[illegible]
Teflon® suction line, strainer tube, 1/8" (ID) x [illegible]	[illegible]

PUMP TUBING

[illegible]	[illegible]
[illegible]	[illegible]

REFRIGERATORS ONLY: COMPLETE EXCEPT FOR CONTROLLERS

Model [illegible] for use with Model [illegible]	[illegible]
[illegible]	[illegible]
Model [illegible] for use with Model [illegible]	[illegible]
[illegible]	[illegible]

accessories for ISCO samplers

BATTERIES. Nicad batteries have a self-discharge rate of one to two percent per day and are better suited than lead-acid or "GEL" batteries for applications where frequent recharging is necessary. Nicad batteries are compact, dry, have an extremely high recharge cycle life, can be left in a run-down condition indefinitely, are freeze proof and can't be overcharged when an ISCO charger is used. A short cord with a water proof connector provides quick and convenient installation.

The ISCO lead-acid battery is less expensive, sealed, and spill proof. It is not a motorcycle-type battery and never requires additional water. A porous filling between the plates greatly reduces the likelihood of freezing if uncharged. It has a water-proof connecting cord and requires a special clamp for mounting. Since the lead-acid battery has a much smaller self-discharge rate, it is better suited for applications where an installation may remain in a dormant condition for a long period of time before being actuated by the Model 1640 Liquid Level Actuator.

Both the ISCO Nicad and lead-acid batteries have a four amp-hour capacity. Battery life specifications are given elsewhere in this brochure. For those who desire to use an automotive battery, a connect cable is available.

Nicad battery. Without charger	60-1684-040
Lead acid battery, with clamp. Without charger	60-1684-062
